A detailed study is presented that evaluates the relative importance of wave plate behavior, scattering processes and absorption phenomena in transferring optical torque from circularly polarized light to optically trapped nematic droplets. A wide range of parameters is considered: droplet diameters between 1 and 15 $\mu$m, birefringence values from 0.15 to 0.26 and trapping beam powers from 50 mW to 400 mW. Wave plate behavior is verified through the dependence of torque on droplet diameter and material birefringence. The dependence of the magnitude of the torque on material birefringence confirms the additional importance of the scattering mechanism. Absorption processes are found to be negligible. © 2004 American Institute of Physics.

\[ \Delta = \frac{2\pi}{\lambda} \ell (n_0 - n_e). \]  

The transfer of spin angular momentum from light to a wide range of materials has been a subject of interest since the original experiments of Beth\textsuperscript{1} on quartz plates. The advent of optical trapping enabled Friese \textit{et al.} to extend experiments to micron-sized calcite fragments that act as wave plates.\textsuperscript{2} Very recently, the optical manipulation of nematic liquid crystal droplets has been demonstrated, for example a fast optical switch was created by Juodkazis \textit{et al.} by viewing an optically trapped droplet, rotating in circularly polarized light, between crossed polarizers.\textsuperscript{3} The same group also demonstrated that optical torque is transferred to a droplet through wave plate behavior,\textsuperscript{4} whereas Savchenko \textit{et al.} proposed that angular momentum can be transferred to a liquid crystalline material through a light scattering process brought about by its birefringent properties.\textsuperscript{5} There is significant interest in using liquid crystalline materials in the transfer of optical torque, but there is some confusion surrounding the mechanisms responsible. This paper presents a detailed study of the relative importance of the possible mechanisms by which optical angular momentum might be transferred to a liquid crystalline droplet; wave plate behavior, scattering, absorption, and the optical Frédéricksz transition. We do not consider lensing effects as these will influence the trapping power rather than the transfer of angular momentum.

The optical torque transferred through wave plate behavior and scattering processes has been considered by Friese \textit{et al.}\textsuperscript{2} and Savchenko \textit{et al.},\textsuperscript{5} respectively. The optical torque $\tau$ on a wave plate in circularly polarized light is modulated such that,

\[ \tau \propto E_0^2 (1 - \cos \Delta). \]  

where $E_0$ is the amplitude of the electric field component of the incident light. The retardance, $\Delta$, describes the phase shift between light field components experiencing the ordinary, $n_0$, and extraordinary, $n_e$, refractive indices of the birefringent medium—and depends on the thickness $t$ of the birefringent material and the wavelength $\lambda$.

A continuous wave 1064 nm Nd:YVO₄ circularly polarized laser beam was used to form the optical trap. In order to trap droplets the laser beam was brought to a focus within a sample using an oil-immersion, Zeiss plan neofluar objective, numerical aperture 1.3. Microscope objectives are known for their high power losses; for the objective and wavelength used a 59±2% loss was expected⁸ and accounted for when calculating trapping powers. Nematic material dispersed in de-ionized water formed suspensions of nematic for when calculating trapping powers. Nematic material dispersed in de-ionized water formed suspensions of nematic droplets after vigorous shaking; 70% of droplets had diameters between 4 \( \mu \)m and 10 \( \mu \)m. Within the droplets, the molecules tend to align along one direction within the center of the droplet, the droplet director, whereas at the edge they lie parallel to the nematic–water interface.⁹ This director arrangement is referred to as the bipolar or dipole configuration. Suspensions were contained between a center cavity microscope slide and a cover-slip in a gap approximately 350 \( \mu \)m wide. A trap depth of 20 \( \mu \)m from the cover-slip was maintained in order to minimize the influence of the sample walls on the fluid flow of the medium near to the droplet.¹⁰

The sample was viewed using white light, between crossed polarizers and a pinhole reduced the illumination on the sample to a spot 15 \( \mu \)m in diameter to prevent surrounding particles from affecting measurements.

Plane polarized light experiencing only \( n_0 \), or \( n_e \), traverses a birefringent medium with unchanged polarization and so does not pass the 2nd polarizer. The period of revolution of a droplet was established by measuring the time between 4 minima on the transmitted light signal collected by an avalanche photodiode, protected by a filter cutting out 1064 nm radiation. IMAQ vision development software from LabVIEW¹¹ was used throughout the studies of the change in optical torque and is plotted in Fig. 2. The peak separations change by 2% loss was expected⁸ and accounted for each particle diameter.

The measured rotation rates of droplets with diameters in the range 1–10 \( \mu \)m are presented on a logarithmic scale in Fig. 1(a) for the sample with birefringence of 0.23. Similar data were recorded for the other materials.

The torque \( \Gamma_v \), due to drag on a solid sphere of diameter \( d \), rotating within a medium of viscosity \( \eta \) about its central axis with an angular frequency \( \nu \), is given by¹³

\[
\Gamma_v = -\pi d^3 \eta \nu.
\]  

The drag on a fluid sphere may not follow Eq. (5) if appreciable circulation within the droplet occurs.¹⁴ However, since the viscosity of the nematic fluid is much greater than the surrounding water, Eq. (5) is a very good approximation of the drag torque on a nematic droplet.

With constant torque applied to a droplet, a linear relationship between the logarithm of the frequency and the particle diameter would be expected; however as is clear from Fig. 1(a) this is not the case. The viscous drag torque of the fluid on the particle calculated using Eq. (5) is presented in Fig. 1(b). The data modulate as expected for a viscous torque that counteracts optical torque originating from wave plate-like behavior. Rotation maxima of the drag torque are observed at particle diameters around 2.5 and 8 \( \mu \)m. At these diameters a \( \pi \) phase difference between the extraordinary and ordinary rays passing through the nematic droplet is probable. The dipole director orientation within a droplet lowers the effective birefringence of a droplet from the bulk birefringence value and thus modifies the modulation of torque associated with a uniaxial medium [Eq. (1)]. The effective birefringence is related only to the bulk birefringence and droplet size.

The average separation of the peaks of the modulating viscous drag torque was calculated for each nematic material and is plotted in Fig. 2. The peak separations change by approximately 2.5 \( \mu \)m over the birefringence range 0.15 to 0.26. The required increase in particle diameter for the retardance to remain constant appears in Fig. 2 to be inversely proportional to the material birefringence, in agreement with Eq. (2) and again confirming the wave-plate mechanism.

The average particle size separation between peaks, filled circles, and the average magnitude of the torque (over all particle sizes), open diamonds, as a function of material birefringence.
of droplet reorientation. With trapping beam powers in excess of 1 MW/cm², it is believed that the optical Freedericksz transition causes this reorienting effect and maintains in-plane orientation within the trap.

In summary, experiments have shown that waveplate-like behavior of nematic droplets and light scattering are predominately responsible for the transfer of optical torque to the droplets from the spin angular momentum of an optical trapping beam. Waveplate-like behavior is dependent on the size and birefringence of the nematic droplet, and causes the observed modulation in the transferred optical torque. Further, the modulation occurs with an amplitude of torque that is highly dependent on the birefringence of the nematic material; evidence of light scattering. A strong linear relationship between the torque and trapping beam power confirms the importance of light scattering and of waveplate-like behavior, and simultaneously eliminates the presence of nonlinear SISLS. The available torque due to photon absorption has been shown to be negligible for nematic droplets. Finally, experimental observations indicate that in the high intensities of an optical trap, the optical Freedericksz transition can cause a reorientation of the director of a nematic droplet toward the plane of polarization of the incident light.

A detailed understanding of which mechanism is dominant in the transfer of optical angular momentum to nematic droplets is important if they are to be used as optical switches or rotors. Nematic droplets can also be rotated and optically switched using electrodes. Since optical and electrical torque can both be applied to nematic droplets, new optical devices may be fabricated from such versatile anisotropic microstructures. This work identifies which mechanism for optical angular momentum transfer dominates for specific conditions.
