Nonlinear Minimum Variance Estimation for Discrete-Time Multi-Channel Systems

Mike J. Grindle, *Fellow, IEEE*, and Shamsher Ali Naz

Abstract—A nonlinear operator approach to estimation in discrete-time systems is described. It involves inferential estimation of a signal which enters a communications channel involving both nonlinearities and transport delays. The measurements are assumed to be corrupted by a colored noise signal which is correlated with the signal to be estimated. The system model may also include a communications channel involving either static or dynamic nonlinearities. The signal channel is represented in a very general nonlinear operator form. The algorithm is relatively simple to derive and to implement.

Index Terms—Estimation, filtering, minimum-variance, nonlinear, optimal estimation, optimization, quadratic cost.

I. INTRODUCTION

THE solution of linear filtering and estimation problems using least squares methods is well established and there are well accepted estimators like the Wiener [1] and Kalman filters [2], [3] that are often used. In this paper, the solution of a very special class of *nonlinear minimum variance (NMV)* estimation problems is considered. The main contribution lies in the definition of a simple estimator for systems with nonlinear communication channels containing delays. The generality of the problem is restricted to ensure a simple real time nonlinear estimator can be derived. The cost function to be minimized involves the variance of the estimation error and a relatively simple optimization procedure and solution results [4].

The system of interest involves both linear and nonlinear subsystems. The estimation problem considered here is to detect the signal of real interest given a measurement which includes noise. To allow for uncertainty, the measurement may also be assumed to include an interference signal that may enter through a parallel channel [5].

One of the main strengths of the technique is that the nonlinear channel dynamics can be represented by a general nonlinear operator. This might involve a set of nonlinear equations or could be a black box model containing unknown code and lookup tables. The model may even be obtained from a neural or fuzzy-neural network. The signal channel includes different

delays and the resulting delayed output of the communications channel is assumed to be measured.

The measurement or observations signal also includes a noise signal which is assumed to derive from the same source but represents uncertainty. This is modeled by a parallel communications path which can represent a possible interference signal. This may not be a physical path but is included for design purposes to shape the interference and measurement noise attenuation characteristics. The solution requires an assumption be made that a particular nonlinear operator has a stable inverse. This operator depends upon the nonlinear channel interference noise model, which is included for design purposes, and may therefore be freely chosen.

The structure for this paper is as follows. The nonlinear system and linear signal model, the cost-function and the solution of the optimal estimation problem are described in Section II and the main theorem is also introduced there. In Section III, a design example that includes nonlinearities is presented. Finally, conclusions are summarized in Section IV.

II. NONLINEAR ESTIMATION PROBLEM

A nonlinear inferential estimation problem is considered involving the estimation of a signal, which enters a multi-channel communication channel including nonlinearities and transport-delay elements [6], [7]. The measurements are assumed to be corrupted by a noise signal, which are correlated with the signal to be estimated for r channels. Signal and noise models are assumed to have linear time-invariant model representations, which is not very restrictive, since in many applications the models for the *signal* and *noise* signals are only *linear time-invariant* approximations. The system, shown in Fig. 1, includes the *nonlinear* signal channel model and linear measurement noise and signal models. These linear r output models are in the same form as in the traditional linear optimal estimation problems [1], [2].

The message signal to be estimated is at the output of a linear block: $s = W_c y$. For greater generality a dynamic cost weighting is introduced and the weighted signal: $s_q = W_q s$ is then to be estimated [8]. If the channel is identity and there is no uncertainty represented by the parallel dotted channel then this is similar to a *Wiener filtering* type of problem.

The polynomial matrix system models may be listed as

$$\text{Signal model : } W_s(z^{-1}) = A_0^{-1}(z^{-1})C_s(z^{-1}) \quad (1)$$

$$\text{Noise model : } W_n(z^{-1}) = A_0^{-1}(z^{-1})C_n(z^{-1}) \quad (2)$$

where the unit delay operator is defined as $z^{-1}x(t) = x(t-1)$.

These models can be taken to be asymptotically stable. Note that the arguments of the polynomial matrices are often omitted

Fig. 1. Nonlinear filtering problem with noise sources, communications channel and channel interference.

for notational simplicity. The signal channel models can include severe nonlinearities that involve both linear and nonlinear dynamics. However, the rest of the system description is defined so that simple results are obtained. The main nonlinear signal channel dynamics with different delays in different channels may be expressed as

$$\mathcal{W}_c = \mathcal{W}_{c1} z^{-\Lambda_0} \quad (3)$$

where $z^{-\Lambda_0}$ denotes a diagonal matrix: $z^{-\Lambda_0} = \text{diag}\{z^{-k_1}, z^{-k_2}, \dots, z^{-k_r}\}$ of the common delay elements in the respective output signal paths and $\Lambda_0 \geq \mathbf{I}$.

A nonlinear parallel channel with dynamics and different channel time-delays may also be defined to have the form

$$\mathcal{F}_c(z^{-1}) = \mathcal{F}_{c0}(z^{-1}) z^{-\Lambda_0}. \quad (4)$$

This may be termed an *uncertainty tuning function*. The parallel path dynamics in Fig. 1 are shown using a dotted line. This is because this channel will probably not exist physically but provides a signal that enters the cost-function to be introduced which enables the noise attenuation to be shaped. It is a fictitious channel which provides additional design freedom when the measurement noise characteristics are uncertain. If the gain goes to zero and the optimal estimator exists then this corresponds with the case where there is no channel uncertainty.

After separating the actual communications channel dynamics into a linear input subsystem and a nonlinear model define the model for the main channel in the form

$$(\mathcal{W}_c f)(t) = (\mathcal{W}_{c1} z^{-\Lambda_0} \mathcal{W}_{c0} f)(t). \quad (5)$$

The output of the nonlinear subsystem $\mathcal{W}_{c1}$ with the explicit channel delays will be denoted as the signal: $\{s_c(t)\}$, where t denotes time at the sample instants.

$$s_c(t) = (\mathcal{W}_{c1} z^{-\Lambda_0} s_0)(t). \quad (6)$$

Note the following rather obvious signal notation is used: $s(t - \Lambda_0) = (z^{-\Lambda_0} s)(t)$ which will denote the signal delayed by different amounts in different signal channels. For simplicity, the nonlinear subsystem: $\mathcal{W}_{c1}$ is assumed to be *finite gain stable*. For stability analysis, the time sequences can be considered to be contained in extensions of the discrete *Marcinkiewicz space* $m_2(R_+, R^n)$ [11]. This is the space of time-sequences with time-averaged square summable signals that have a finite power.

The input and noise generating processes have an innovations signal model with white noise signal input $\varepsilon(t) \in R^q$, and it may be assumed to be zero mean with covariance matrix $\text{cov}[\varepsilon(t), \varepsilon(\tau)] = I \delta_{t\tau}$, where $\delta_{t\tau}$ denotes the *Kronecker delta-function*. The combined signal source and noise signal $f(t) \in R^r$ is given as

$$f(t) = y(t) + n(t). \quad (7)$$

The infinite-time estimation problem where the filter is assumed to be in operation from an initial time: $t_0 = -\infty$, is considered. The signals shown in the closed-loop system model of Fig. 1 may be listed as follows:

$$\text{Noise : } n(t) = W_n \varepsilon(t) \quad (8)$$

$$\text{Input signal : } y(t) = W_s \varepsilon(t) \quad (9)$$

$$\text{Channel input : } f(t) = y(t) + n(t) \quad (10)$$

$$\text{Linear channel subsystem : } s_0(t) = (\mathcal{W}_{c0} f)(t) \quad (11)$$

$$\text{Channel interference : } n_c(t) = (\mathcal{F}_c \varepsilon)(t) \quad (12)$$

$$\text{Nonlinear channel subsystem :}$$

$$s_c(t) = (\mathcal{W}_{c1} s_d)(t) \quad (13)$$

$$\text{Nonlinear channel input :}$$

$$s_d(t) = z^{-\Lambda_0} s_0(t) = s_0(t - \Lambda_0) \quad (14)$$

$$\text{Observations signal : } z(t) = n_c(t) + s_c(t) \quad (15)$$

$$\text{Message signal to estimate :}$$

$$s(t) = W_c y(t) = W_c W_s \varepsilon(t) \quad (16)$$

$$\text{Weighted message signal : } s_q(t) = W_q W_c y(t) \quad (17)$$

$$\text{Estimation error signal : } \tilde{s}(t|t) = s(t) - \hat{s}(t|t). \quad (18)$$

In some problems, W_c may represent part of the communications path so that: $W_c = W_{c0}$. The *power spectrum* for the combined linear models can be computed, noting these are linear subsystems, using: $\Phi_{ff} = (W_s + W_n)(W_s^* + W_n^*)$, where the notation for the adjoint of W_s implies: $W_s^*(z^{-1}) = W_s^T(z)$, and in this case the z denotes the z -domain complex number. The *generalized spectral-factor*: Y_f may be computed using: $Y_f Y_f^* = \Phi_{ff}$, where $Y_f = A_0^{-1} D_{f0} = D_f A^{-1}$. The system models are assumed to be such that D_{f0} is a *strictly Schur*, r square, polynomial matrix [12] satisfying

$$D_{f0} D_{f0}^* = (C_s + C_n)(C_s^* + C_n^*) \quad (19)$$

The *right-coprime* polynomial matrix may now be defined as

$$[C_f \quad D_f]A^{-1} = [W_q W_c W_s \quad Y_f]. \quad (20)$$

Observe that the noise and signal models are correlated. However, W_s is normally low-pass and W_n is normally high-pass and the results for the special case of the linear problem, with no channel dynamics, will be similar to those for the usual *Wiener* or *Kalman filtering* case [1], [2].

A. Proposed Solution for Nonlinear Estimation Problem

The estimation problem is concerned with finding the best estimate of the signal $s(t)$ in the presence of an interference noise term. The minimum variance *optimal deconvolution problem* [13] involves the minimization of the estimation error

$$\tilde{s}(t|t-\ell) = s(t) - \hat{s}(t|t-\ell) \quad (21)$$

where $\hat{s}(t|t-\ell)$ denotes the optimal nonlinear estimate of the signal $\{s(t)\}$ at time t , given the observations: $\{z(\tau)\}$ over the semi-infinite interval: $\tau \in (-\infty, t-\ell]$ up to time $(t-\ell)$. The scalar ℓ may be positive or negative and as noted

$$\begin{aligned} \ell = 0 &: \text{Filtering} \\ \ell < 0 &: \text{Fixed lag smoothing} \\ \ell > 0 &: \text{Prediction.} \end{aligned}$$

The weighted estimation error cost-function which is to be minimized has the form

$$J = \text{trace} \left\{ E \left\{ W_q \tilde{s}(t|t-\ell) (W_q \tilde{s}(t|t-\ell))^T \right\} \right\} \quad (22)$$

where $E\{\cdot\}$ denotes the expectation operator and W_q denotes a linear dynamic cost weighting function matrix which is assumed to be strictly minimum phase, square and invertible. The estimate $\hat{s}(t|t-\ell)$ is assumed to be generated from a nonlinear, estimator of the form

$$\hat{s}(t|t-\ell) = H_f(t, z^{-1})z(t-\ell) \quad (23)$$

where H_f denotes a minimal realization of the optimal nonlinear estimator. Since an infinite-time ($\tau_0 \rightarrow -\infty$) problem is of interest no initial condition term is required. The following theorem applies.

Theorem: Optimal Estimator for Nonlinear Systems: The assumption is made that $W_{c0}Y_f$ and $z^{-\Lambda_0}$ commute and that the operator $(\mathcal{F}_{c0} + W_{c1}W_{c0}Y_f)$ has a stable inverse. The nonlinear *deconvolution filter* ($\ell = 0$), *predictor* ($\ell > 0$), or *smoother* ($\ell < 0$), to minimize the variance of the estimation error (22), for the system described in Section II, can be calculated from the *spectral factor*, *Diophantine*, and *operator* equations. The spectral factor $Y_f = A_0^{-1}D_{f0}$, where D_{f0}^{-1} is asymptotically stable, is defined from the polynomial matrix

$$D_{f0}D_{f0}^* = (C_s + C_n)(C_s^* + C_n^*). \quad (24)$$

Right-coprime polynomial matrices (C_f, D_f) and A satisfy

$$[C_f \quad D_f]A^{-1} = [W_q W_c W_s \quad Y_f]. \quad (25)$$

Fig. 2. Nonlinear estimator structure.

The polynomial operators G_0 and F_0 may now be obtained from the *minimal degree* solution (G_0, F_0) , with respect to F_0 , of the following Diophantine equation:

$$F_0A + G_0z^{-\Lambda_0-\ell} = C_f. \quad (26)$$

Estimator: The optimal casual, nonlinear estimate $\hat{s}(t|t-\ell) = \mathcal{H}_f(t, z^{-1})z(t-\ell)$ for the system described in Section II, to minimize the average variance of the estimation error (22), is given as

$$\mathcal{H}_f = W_q^{-1}G_0(\mathcal{F}_{c0}A + W_{c1}W_{c0}D_f)^{-1}. \quad (27)$$

Minimum Cost: The *minimum variance* may be computed

$$J = \text{trace} \left\{ \frac{1}{2\pi j} \oint_{|z|=1} F_0 F_0^* \frac{dz}{z} \right\}. \quad (28)$$

Proof: The proof follows. ■

Remarks:

- The assumption is required that $(W_{c0}Y_f$ and $z^{-\Lambda_0})$ commute, which is certainly satisfied if the delays are the same $z^{-\Lambda_0} = z^{-k}I$, or if these models are diagonal.
- Note that the *Minimum Variance* follows from (28) for the system with uncertainty, and it does not, surprisingly, include the nonlinear sensor characteristics.
- The structure for the resulting estimator is shown in Fig. 2.

B. Solution

To obtain an expression for the *weighted estimation error* $s_q = W_q \tilde{s}(t|t-\ell)$, note from the (7)–(9)

$$f = A_0^{-1}C_n\varepsilon + A_0^{-1}C_s\varepsilon. \quad (29)$$

A realization of $\{f(t)\}$ can be obtained using the spectral factor defined above as

$$f = A_0^{-1}D_{f0}\varepsilon \quad (30)$$

where D_{f0} satisfies (19). Also recall the weighted message signal is given from (17) as

$$s_q = W_q W_c W_s \varepsilon. \quad (31)$$

Estimation error: From equations: (1), (20), and (31), obtain

$$\tilde{s}_q(t|t-\ell) = s_q(t) - \hat{s}_q(t|t-\ell) = W_q (W_c W_s \varepsilon(t) - \mathcal{H}_f z(t-\ell)). \quad (32)$$

Recall from (15) that the observations $z = n_c + s_c$ and substituting from (32)

$$\begin{aligned} \tilde{s}_q(t|t-\ell) &= C_f(z^{-1})A^{-1}(z^{-1})\varepsilon(t) \\ &\quad - W_q \mathcal{H}_f (n_c(t-\ell) + s_c(t-\ell)). \end{aligned}$$

From (10), (12), (13), and (14) $s_c(t) = (\mathcal{W}_{c1}s_d)(t)$ and $n_c(t) = (\mathcal{F}_c\varepsilon)(t)$ obtain

$$\begin{aligned}\tilde{s}_q(t|t-\ell) &= C_f(z^{-1})A^{-1}(z^{-1})\varepsilon(t) \\ &\quad - W_q\mathcal{H}_f((\mathcal{F}_c\varepsilon)(t-\ell) + (\mathcal{W}_{c1}s_d)(t-\ell)) \\ &= C_f(z^{-1})A^{-1}(z^{-1})\varepsilon(t) \\ &\quad - W_q\mathcal{H}_f((\mathcal{F}_{c0}z^{-\Lambda_0}\varepsilon)(t-\ell) \\ &\quad + (\mathcal{W}_{c1}z^{-\Lambda_0}s_0)(t-\ell)).\end{aligned}\quad (33)$$

Also using equations (11), (16), and (30)

$$\begin{aligned}\tilde{s}_q(t|t-\ell) &= C_f(z^{-1})A^{-1}(z^{-1})\varepsilon(t) \\ &\quad - W_q\mathcal{H}_f((\mathcal{F}_{c0}z^{-\Lambda_0}\varepsilon)(t-\ell) + (\mathcal{W}_{c1}z^{-\Lambda_0}W_{c0}Y_f\varepsilon)(t-\ell)).\end{aligned}$$

Under the assumption that $W_{c0}Y_f$ and $z^{-\Lambda_0}$ commute, then

$$\begin{aligned}\tilde{s}_q(t|t-\ell) &= C_f(z^{-1})A^{-1}(z^{-1})\varepsilon(t) \\ &\quad - W_q\mathcal{H}_f((\mathcal{F}_{c0}z^{-\Lambda_0}\varepsilon)(t-\ell) \\ &\quad + (\mathcal{W}_{c1}W_{c0}Y_fz^{-\Lambda_0}\varepsilon)(t-\ell)) \\ &= C_f(z^{-1})A^{-1}(z^{-1})\varepsilon(t) \\ &\quad - W_q\mathcal{H}_f(\mathcal{F}_{c0} + \mathcal{W}_{c1}W_{c0}Y_f)\varepsilon(t-\Lambda_0-\ell).\end{aligned}\quad (34)$$

The first term may be simplified using the Diophantine equation $F_0A + G_0z^{-\Lambda_0-\ell} = C_f$ and hence

$$\begin{aligned}\tilde{s}_q(t|t-\ell) &= (F_0 + G_0A^{-1}z^{-\Lambda_0-\ell})\varepsilon(t) \\ &\quad - W_q\mathcal{H}_f(\mathcal{F}_{c0} + \mathcal{W}_{c1}W_{c0}Y_f)\varepsilon(t-\Lambda_0-\ell) \\ &= F_0\varepsilon(t) + G_0A^{-1}\varepsilon(t-\Lambda_0-\ell) \\ &\quad - W_q\mathcal{H}_f(\mathcal{F}_{c0} + \mathcal{W}_{c1}W_{c0}Y_f)\varepsilon(t-\Lambda_0-\ell).\end{aligned}\quad (35)$$

C. Optimization

To compute the *optimal nonlinear estimator*, first inspect the form of the *weighted estimation error* in (35) and advance by $t + \ell + \Lambda_0$ to obtain

$$\begin{aligned}\tilde{s}_q(t + \ell + \Lambda_0|t + \Lambda_0) &= F_0\varepsilon(t + \ell + \Lambda_0) \\ &\quad + [G_0A^{-1} - W_q\mathcal{H}_f(\mathcal{F}_{c0} + \mathcal{W}_{c1}W_{c0}Y_f)]\varepsilon(t).\end{aligned}\quad (36)$$

The signal $F_0\varepsilon$ above will first be considered. The polynomial matrix term F_0 in (36) may be expanded as a sequence of terms in the unit advance operator $\{z, z^2, z^3, z^4, \dots, z^{\ell+\Lambda_0}\}$. It follows that the first term in (36) is dependent upon the future values of the white noise signal components $\varepsilon(t+1), \varepsilon(t+2), \varepsilon(t+3), \dots, \varepsilon(t+\ell+\Lambda_0)$. The second group of terms in (36) (in the square brackets) are all dependent upon past values of the white noise signals, whereas the first term depends only upon future values. It follows that these two groups of terms are statistically independent and the expected value of the cross terms is null.

Also note that the first term on the right-hand side of (36) is independent of the choice of estimator. It follows that the smallest variance is achieved when the remaining terms are set to zero.

Assuming the existence of a finite gain stable causal inverse to the nonlinear operator the *optimal estimator* is obtained by setting this second group of terms to zero, noting

$$\begin{aligned}Y_f &= D_f A^{-1} : \\ \mathcal{H}_f &= W_q^{-1}G_0(\mathcal{F}_{c0}A + \mathcal{W}_{c1}W_{c0}D_f)^{-1}.\end{aligned}\quad (37)$$

This completes the solution of the theorem.

Also note that assumption preceding the main theorem has to be satisfied for the results to apply so a silly choice of sensor characteristic would mean that the results would not hold. If the assumption does hold the minimum variance only depends upon the linear signal and noise model terms. The expression for the estimation error depends on both linear and nonlinear terms, however, all the nonlinear terms when combined with the nonlinear estimator add to zero. Thus, this cost may be considered an ideal and if the uncertainty channel was null it would require an inverse to be computed for the sensor/channel characteristic. Thus, it appears independent of any sensor characteristic. In practice there will be uncertainty and the estimator will not try to cancel the nonlinear sensor/channel characteristic but the absolute minimum cost remains the same as defined by (28).

III. DESIGN ISSUES AND EXAMPLES

The computation of the estimator is relatively straightforward. The polynomial matrix equations can be solved using the Matlab polynomial toolbox PolyX. Given these matrices the estimator may be implemented neatly, as shown in Fig. 2. The NMV filter involves matrix calculations so its on-line computational might be large but this is not true because the major matrix calculations are offline to be conducted during the design phase and these have no impact in the implementation phase. The computational complexity and implementation issues of the NMV filter are discussed in some detail in [25].

The selection of the *uncertainty tuning function* $\mathcal{F}_{c0}$ is a dual problem to the selection of optimal control cost function weightings [7]. The requirement on the nonlinear operator mentioned before the theorem to have a stable inverse is of course mandatory. A simple starting point is therefore to assume the uncertainty model $\mathcal{F}_{c0}$ is a constant and of a small magnitude. This corresponds to the situation where the uncertainty is simply white noise added at the output of the communications channel before it enters the estimator (see Fig. 1). Uncertainty is, of course, often associated with high frequency behavior, and hence a simple linear lead term might be used to represent the frequency response of $\mathcal{F}_{c0}$ as in the example which follows.

An exhaust gas oxygen sensor or lambda sensor is a key sensor in an automotive engine fuel control feedback loop. The electronic control unit uses the sensor's input to balance the fuel mixture, leaning the mixture when the sensor reads rich and enriching the mixture when the sensor reads lean. The NMV example assumes the sensor measures the residual oxygen in the exhaust gas and passes the information to the engine control unit (ECU), and based on this the ECU adjusts the optimum air-fuel mixture in the mixture control unit. The lambda or oxygen sensor is located at some distance from the point of interest due to which there is also a significant delay in the measurement as shown in Fig. 3.

Fig. 8. Comparison between actual and estimated Lambda using the UEGO sensor.

$$W_n(z^{-1}) = \frac{0.03681z^{-1}}{1 - 0.9632z^{-1}}. \quad (40)$$

The universal exhaust gas oxygen (UEGO) sensor uses the changes of voltage that are representative of the oxygen levels in the reference and test chambers of the sensor to drive an electronic control unit for feedback control. The exhaust gas oxygen (EGO) sensor is an alternative which is an electrochemical cell used to measure the oxygen content of an engine's exhaust. In closed-loop operation this signal is used to monitor the fuel mixture. The static nonlinear characteristics of the UEGO and EGO sensors are shown in Fig. 4(a) and (b), respectively.

Three cases of the NMV estimation problem are now considered. The minimum value of the cost for the system which includes uncertainty follows from (28) and may be computed as: $J = 1.08e - 5$. In first case the EGO sensor is used with the

uncertainty tuning function shown in Fig. 5, but the fictitious parallel uncertainty model is not included in the simulation, so the computed cost will not be expected to coincide with this theoretical figure. The time response results are shown in Fig. 6 and Table I.

In the second case, the UEGO sensor was used and the results obtained in this case are shown in Figs. 7 and 8 and Table II. In the last case, both the EGO and UEGO sensors are used together and summed with two equally weighted estimators. The results obtained in this case are as shown in Figs. 9 and 10 and Table III.

In all the above cases the estimator depends on the choice of *uncertainty tuning function* $\mathcal{F}_{c0}$ to obtain a stable inverse of $\mathcal{F}_{c0}A + W_{c1}W_{c0}D_f$. The choice of zero-frequency gain (DC gain) and the cutoff frequency of $\mathcal{F}_{c0}$ are important in obtaining a realizable design for the NMV estimation algorithm. Clearly the estimation error reduces when the uncertainty tuning gain

decreases so long as an optimal filter actually exists, which explains much of the behavior in the table of values. The dynamic response should really reflect the type of uncertainty expected or if the parallel uncertainty channel exists then it will depend upon the physical model.

Comparison With Alternative Approaches: H_∞ filtering: The H_∞ minimax estimator for nonlinear systems may handle constraints [22] and provides an alternative that may be particularly useful for systems with significant nonlinearities. The mixed H_2 and H_∞ minimization problem enables traditional variance based estimation criteria to be considered but also allow uncertainty to be taken into account, considered by [23]. The most practical way to implement the H_∞ estimator is in discrete form but there is a much greater level of mathematical abstraction involved [24].

Extended Kalman filter: A comparison is described in [21] and [25] that includes detailed discussions about the performance of NMV filter with the extended Kalman filter implemented on the ball and beam system in real time. The comparison results are shown in Fig. 11. The minimum variance for the NMV estimator was calculated as 0.00084 and for the EKF as 0.0035. We can also see from the Fig. 11 that the performance of the NMV estimator is good in comparison to the EKF and is in accordance with the minimum variance results.

The main strength of the approach is that for a restricted class of systems, where the technique is applicable, it provides a very simple solution to a difficult nonlinear estimation problem.

IV. CONCLUSION

The proposed nonlinear filter is applicable to a rather special class of nonlinear estimation problems. However, it is believed to be acceptable to reduce the generality of the problem considered, to obtain a very practical nonlinear estimation algorithm. The solution is relatively easy to understand and to implement. For example, the theoretical basis, however restricted, is much easier to understand than H_∞ or particle filtering, which is important in applications.

Other nonlinear filtering techniques like the extended Kalman filter do of course involve approximations and they are not optimal estimators. The solution proposed here does not involve the same type of approximation if the uncertainty tuning function is representative. However, a question of interest is whether the optimal estimator for the system containing the fictitious uncertainty model is more accurate than an approximately optimal estimator for the actual system. A comparison with an EKF in [21], using a Labview implementation, suggests the new class of estimators is good for a real application.

ACKNOWLEDGMENT

The authors would like to thank Dr. P. Majecki for his discussions on applications and to the Engineering and Physical Sciences Research Council for financial support.

Mike J. Grimble (M'75–SM'78–F'93) was born in Grimsby, U.K. He received the B.Sc. (Coventry), M.Sc., Ph.D., and D.Sc. degrees from the University of Birmingham, U.K.

His research on the Industrial Automation Group at Imperial College was concerned with the modeling and control of cold strip mills. In 1981, The University of Strathclyde, Glasgow, U.K., appointed him to the Professorship of Industrial Systems, and he established the Industrial Control Centre more than two decades ago. His Centre is concerned

with industrial control problems, particularly those arising in the automotive,

aerospace, process control, wind energy, metal processing, marine, electrical power and water industries. His research interests include nonlinear filtering and control systems, adaptive control, H_∞ robust, multivariable design, optimal control, and estimation theory.

Dr. Grimble is the Managing Editor of the *International Journal of Adaptive Control and Signal Processing* and of the *International Journal of Robust and Non-linear Control*, and he was also recently appointed the Editor of *Optimal Control Applications and Methods*, all published by Wiley. He was the Editor of the Prentice-Hall International series of books on *Systems and Control Engineering* and also the Prentice-Hall series on *Acoustics Speech and Signal Processing*. He is currently a joint editor of the Springer Monograph Series on *Advances in Industrial Control* and also the Joint Editor of the Springer text book series on *Control and Signal Processing*. He established a university consultancy company Industrial Systems and Control, Ltd., for which he acts as the technical director and also developed the Applied Control Technology Consortium, which is an international technology transfer and training organization with support from over 30 companies in Europe and North America. These have been successful in helping companies to adopt new technology for about two decades and they compliment the industrial research services of the centre. The Institution of Electrical Engineers presented him with the Heaviside Premium in 1978 for his papers on control engineering. In 1979, he was awarded jointly the Coopers Hill War Memorial Prize and Medal by the Institutions of Electrical, Mechanical and Civil Engineering. The Institute of Measurement and Control awarded him the 1991 Honeywell International Medal. He was awarded an IEEE Fellowship in 1992, and he was recognized at the 1993 Edinburgh International Science Festival as one of Scotland's four most cited Scientists. He was appointed a Fellow of the Royal Society of Edinburgh in 1999. He was awarded jointly the Asian Journal of Control best paper award for 2002–2003. He was recently awarded the Institution of Engineering and Technology Heaviside Medal for achievements in Control in 2008.

Shamsher Ali Naz was born in Pakistan on January 1, 1970. He received the B.Sc. degree in electrical engineering from the University of Engineering and Technology, Lahore, in 1993. He is currently working towards the Ph.D. degree in the University of Strathclyde, Glasgow, U.K.

From 1995 to 2005, he was with National Centre for Physics, Quaid-i-Azam University Campus, Islamabad.
