The Strathprints institutional repository (https://strathprints.strath.ac.uk) is a digital archive of University of Strathclyde research outputs. It has been developed to disseminate open access research outputs, expose data about those outputs, and enable the management and persistent access to Strathclyde's intellectual output.
We consider an alternative model by introducing a two-phase evaluation strategy. A query $Q$ is decomposed into an event driven primary filter query $Q'$, which incrementally gathers relevant data from the input stream, and another query $Q''$ which consumes this data as it becomes available. Evaluation of $Q(s)$ is then equivalent to $Q''(Q'(s))$. The importance of the separation is that it allows the first phase $Q'$ to be expressed in a non-Turing complete algebra which may therefore be generally amenable to event-based interpretation. The second phase $Q''$ may be expressed in an arbitrary higher-order language, so long as its execution takes no longer than the extraction of the next input instance from the input stream.

We consider a type algebra is used to express the first-phase query. This builds on previous work, which shows how traditional programming language types may be given a semantics within XML, therefore allowing their projection onto XML resources. A side-effect of this definition of projection is that instances of a type may be extracted in a form available for computation within a traditional domain. The use of type projection in this context also allows $Q''$ to be statically typed according to the type filter used for $Q'$, which itself may be deduced by inference over $Q''$. A mechanism for translating a type into a network of event driven automata, which has the effect of gathering all data captured by that type from a semistructured input stream, is described. Although at an early stage of investigation, initial results suggest this approach provides a credible alternative to stream-based querying in at least some application domains.
tions; the same of course is true for any single query language with sufficient expressive power to handle any reasonable range of queries.

We propose a significant departure from this methodology which we show works well for certain classes of application. The query is coded as a function in a Turing-complete programming language, with the assumption that the execution of this function will occur within acceptable bounds if its input can be isolated and passed to it as a process separated from the parsing of the input stream. This function could represent the query in its entirety, but in this domain the whole query is more likely to be represented by the repeated application of the function to instances of its input as they are extracted from the XML stream.

The function is typed according to its input, and this type is used to generate a deterministic state automata based input filter which extracts corresponding values from the XML input stream. These values are then passed, as they occur, to the query. In this way fully general queries can proceed in parallel with the parsing of the input. This builds on our previous work [5, 14, 15, 6, 10], in which we show how traditional programming language types may be given a semantics within XML, therefore allowing their extraction from XML resources.

The method will only work well if the query function is short-lived, and its type represents a significantly small subset of the XML stream; however we believe there exist many instances of this pattern. The main properties of the method are as follows:

- only the type-based extraction requires to be translated into the event-based paradigm
- only the second part of the query requires to be expressed, as the filter can be automatically generated from it
- the two phases of the execution can proceed in parallel

Compared with single-phase deterministic automata translations from XPath or XQuery, the method seems likely to work relatively well for complex queries over core regular data within a loosely structured stream, while it is likely to work relatively badly for simple queries over data that is inherently unstructured. The tradeoffs with respect to simplicity of expression and efficiency are complex and require further investigation, but in this paper we have at least shown credibility in these domains with respect to some classes of application.

In more generality, not considered further in this paper, the same basic two-part query framework may be used entirely within the XML standards domain, by expressing the filter by a projection defined over XML Schema. Instances of XML would then be generated by the first phase, allowing the secondary part to be expressed in any XML query language. One particularly interesting aspect of this is that, if the entire data stream is known to be valid with respect to a given schema, then the soundness of the filter may be statically assessed, and furthermore user-level tools for generating it from the XML Schema stream description could be envisaged.

2. A MOTIVATING EXAMPLE

For motivation, an example streamed application is coded in Java using various alternative implementation techniques, namely SAX, XPath, and TypEx, the system based on the approach described. SAX only creates temporary data structures to report parsing events which need to be transferred manually into the application specific data model for processing. The XPath code uses an XPath expression to define a superset of the required data, in conjunction with DOM code to perform the required query; the TypEx code uses a Java class definition to define a superset of the required data, in conjunction with a method of that class to query it. In the cases of XPath and TypEx the initial extraction may be performed incrementally and processed in parallel with the code that uses the extracted values, whereas in the SAX application the entire processing must be performed within the parsing callbacks.

The example is a news ticker application, which extracts news items from an arbitrary XML stream. Schema information of the expected stream is incomplete and restricted to the relevant data. The application programmer knows that there are item elements which contain at least two direct child elements named title and description. Both these elements contain only textual content and can occur only once within any item. This data may be embedded at any point in the source and additional content may appear beneath item elements. The application is to display the content of these two fields as they are detected within an unbounded stream of XML.

2.1 Parsing Event Based Model

An example of an approach in which the query is directly contained in the application code is the event-based abstraction model used by SAX. Mappings between parsing events and the data model used are spread over various callback methods, making it hard to understand and thus maintain. The mixture of selection and computation also increases the coupling between user-specified computation and parsing process and is thus undesirable.

Listing 1: The SAX handler for the news ticker

```
public class NewsHandler extends DefaultHandler {
    private StringBuffer _title, _description;
    private Stack elements = new Stack();
    public void characters(char[] ch, int start, int length) {
        if (elements.search("item") == 2) {
            if (elements.search("title") == 1)
                _title.append(ch, start, length);
            if (elements.search("description") == 1)
                _description.append(ch, start, length);
        }
    }
    public void startElement(String namespaceURI,
            String localName, String qName, Attributes atts) {
        elements.push(qName);
        if (qName.equals("item")) {
```
Listed 1 shows that the required state information is maintained by using a stack containing all opened tags (line 15). String buffers are created once an opening item tag is found. Upon occurrence of character data the top two elements of the stack are checked. If they fit the structural constraints, the content is appended to the relevant buffers. The content of these buffers is printed when the end of a news item is detected. Note that this implementation does not verify order, multiplicity or even existence of required fields, but just checks that identified fields suffice the structural constraints. Other constraints would need to be checked using a more complicated handler or a partial schema validation process, which is currently not part of any of the relevant standards.

2.2 XPath/DOM Based Model
The combination of XPath [16] and DOM allows a different approach. Programs specify the desired set of nodes using a path expression, and operate over the results using tree traversal code. XPath expressions are navigation expressions over tree structured data which are sent to an execution engine in a similar fashion as embedded SQL statements. Selection is mechanically performed by the system and returns a collection of trees, requiring tree traversal code in the user specified computation. Typically a superset of the data required is returned because XPath returns the entire subtrees rooted at the selected nodes, regardless of the data requirements of the subsequent computation. However, as there is no strong coupling between the two phases, it cannot be guaranteed that the returned data actually satisfies the computational needs.

Listing 2: The same application using XPath

```java
public class BBCNewsXPath {
public static void main(String[] args) {
    DocumentBuilderFactory factory = DocumentBuilderFactory.newInstance();
    DocumentBuilder builder = factory.newDocumentBuilder();
    Node doc = builder.parse(new URL(args[0]).openStream());
    NodeList results = XPathAPI.selectNodeList(doc,
        "//item[description and child::text()]"
        + "[title and child::text()]"
        + "[count(title)=1]"
        + "[count(description)=1]");
    for (int i=0; i<results.getLength(); i++) {
        Node result = results.item(i);
        Element aItem = (Element) result;
        NodeList titles = aItem
            .getElementsByTagName("title");
        String title =
            ((Element) titles.item(0))
            .getFirstChild().getNodeValue();
        NodeList descriptions = aItem
            .getElementsByTagName("description");
        String desc =
            ((Element) descriptions.item(0))
            .getFirstChild().getNodeValue();
        System.out.println( title + "\n" + desc);
    }
}
}
```

The program shown in Listing 2 uses the single XPath statement stretching from lines 12–15 to declare the navigational steps required to select the relevant data. The XPath execution engine returns a NodeList containing the selected nodes (line 10). The loop starting in line 16 iterates through this list and extracts the data from the relevant text nodes using the DOM API, and in particular the method getElementsByTagName which selects nodes based on their name. Structural checks upon the input format have been added to the XPath query in Listing 2, which allows them to be omitted from the result processing code which otherwise would contain explicit structural checking. The XPath implementation used is not streaming, but this does not affect the purpose of the example.

2.3 Type Projection Based Model
The approach suggested by this paper has been implemented in the TypEx system. The extraction phase identifies data that may be relevant for the query by means of a filter type and binds this data to an instance of this type for use in the second phase. Since the computation is specified in terms of the filter type, the returned instances of this type will always contain a superset of the information required.

Listing 3: The filter class item

```java
public class item {
    String title , description ;
    public String toString() {
        return title+"\n"+description;
    }
}
```

In our example application, the class used to store and print news items is also used as the filter type (Listing 3). This defines the data extraction in terms of the host programming language and acts as a data model for the following computation, ensuring a match between the two phases and a seamless integration with the language. The actual com-
3. TYPE BASED EXTRACTION

In this section we outline the translation of a core type language into a network of co-operating, deterministic automata. The resulting network is capable of extracting values of those types.

The type language includes both record and list constructors, but does not allow anonymous lists to occur as they have no semantic projection in XML. In addition, lists cannot occur at the toplevel, as this would be incongruous with the purpose of the mechanism, which is to release typed data as soon as possible. A grammar for the type language is given below.

```plaintext
typedef ::= label : type
        type ::= record | scalar
        record ::= { label1: field1, ..., labeln: fieldn }
        field ::= scalar | record | list [ type ]
        scalar ::= int | string
```

A type expression is translated into a set of named component types as shown by the following example:

```plaintext
p : { a: int, b: list [{ d: int }], c: { d: int } }
```

is transformed into

```plaintext
p : T1
T1: { a: T2, b: list[T3], c: T3 }
T2: int
T3: { d: T2 }
```

Each type \( T_i \) in this representation is mapped to an automaton, whose job is to extract an instance of that type from the input stream and return it as a value. The topology produced by this example is shown in Figure 1. The size of the automata network equals the size of the corresponding type graph plus one for the additional sink machine.

The root and sink machines always occur as single instances; the others are generated according to the individual type components. Each internal connection is a two-way link, passing input events in one direction and results in the other. Only one machine at a time actively processes events; a machine becomes active when it receives an init() event, and remains so until either a return() or fail() event is passed back to its initiator. Non-active machines pass events on to the currently active machine. Events are propagated synchronously in that they are not passed to the active machine until the previous event has been processed; this avoids synchronicity problems with the return events being passed back up the chain.

Figure 1: The example automata network

The following messages are defined: open(l), close(l), text(v), init(l), return(v), and fail(). A parameter \( l \) stands for a label corresponding to an XML tag label, and a parameter \( v \) stands for a value. open(l), close(l) and text(v) are events corresponding to a simplified input stream, and correspond to the textual form of the XML being processed. init(l), as described, causes a machine to become active; its parameter is a label which, when subsequently received within a close(l) message, will cause it to pass control back to its initiator. This is either by means of a return(v) message, in the case it has been able to extract a value corresponding to its type from the input stream, and by means of a fail() message otherwise. There are four different classes of machines: entry, sink, scalar and record, as defined by the following behaviours:

- **Entry**: discard every event until an open(l) occurs, where \( l \) is the label corresponding to the name of the top-level typedef. At this point, init(l) is passed on to the machine corresponding to the type of the top-level typedef, which then becomes the active machine. Further events are passed to this machine until either a return(v) or fail() is received from it. On a return(v), the parameter \( v \) is passed on to the network’s receiver; on fail(), no further action occurs.

- **Sink**: the purpose of this machine is to discard an XML subtree, which cannot be of interest to the extraction. On receipt of init(l), it becomes the active machine; its only required function is to discard events
The automata networks within TypEx form the middle layer of the system architecture. Below this layer an event handler translates parsing events generated by an underlying XML parser into automata events. Above the automata layer is the transformation layer, which generates networks from filter specifications and transforms extracted data graphs into instances of the specified type. The top layer is the programmer visible API, which allows the specification of an input source and associated filter types. It allows multiple listeners per filter and multiple filters per data stream, affording a degree of parallelism in the query process.

Each automaton is implemented as a Java class. Automata networks are generated using reflection to examine the field types and names of filter types. Reflection is also used during data instantiation process.

5. EXPERIMENTAL RESULTS

To determine the viability of our approach, we have processed a more complex example query than the one discussed in Section 2. The data set under consideration has been generated using the XMark benchmark [13] scalable data generation tool and describes auction site details containing items for sale, persons (bidders and sellers) and some more information not relevant for our purposes. In particular, we have queried large XML files (up to 11GB in size) for people (with attributes such as name, address, etc.). We compare programs based on SAX, DOM XPath and TypEx both in terms of the complexity of the code and their runtime performance. The number of lines have been taken as a simple measure of the complexity of the code (Table 1).

Table 2: Length of Query Execution (s)

Table 1 supports the observation gained from the news ticker example and illustrates the conciseness possible using the TypEx approach. The SAX program, contains a mix of high-level application code and low-level parsing callbacks and results in an order of magnitude increase of code. DOM and XPath approaches lie between these two extremes and are almost identical because of their common tree traversal code.

The SAX query execution time scales linearly with the size of the input data and its memory usage depends only the level of element nesting. DOM is unsuitable for streaming due to its inherent whole document approach. As the input size increases, the time taken to complete the query increases more than linearly, while the memory usage increases linearly. With an 100 MB source file, the query fails to complete due to an OutOfMemory error using a heap size of 512 MB. We were unable to obtain a complete implementation of XPath to operate upon streaming data. The implementation we used for this experiment, Xalan/J, is backed by a incrementally built tree structure, and thus scales similarly to a DOM implementation in space. It does not however, provide results in an incremental fashion and thus does not allow a direct comparison with either SAX or TypEx. TypEx, while slower to execute than the equivalent SAX program also scales linearly with the size of the input data. The memory requirements are determined by the size of the extracted type, i.e. are independent of the size of the document. We have used it to successfully query inputs of up to 1 GB in size.
6. RELATED WORK

To the best of our knowledge, this is the first attempt of using types as filters in a two stage stream query process. The requirements for stream processing have been identified in [3] and elsewhere.

Much of the effort concentrates on implementing the XPath [16] language over streams. A number of independent efforts are proceeding, such as XMLTK [2], SPEX [11], and XSQ [12]. Green et al. [7] describe the implementation of an XPath subset using a lazily generated network of DFA and provide a comparison with other XPath implementations over streams. The work concentrates on the construction of a single automata network representing a large number of XPath queries which are executed simultaneously. Olteanu et al. [11] describe the translation of a subset of XPath expression into equivalent expression using only forward axis, which can then be efficiently processed by their SPEX XPath system using a network of event driven automata. Finally the XSQ system [12] is based upon push-down transducers with associated buffers and aims at complete XPath support.

A more recent approach by Ludäscher et al. [9] describes the implementation of the computationally complete query language XQuery over streaming data, using transducer networks derived from a query expression. Their XSM system optimises the derived network based on static analysis and available schema information. Optimisation strategies used may prove useful for our approach.

Type projection is introduced in [5] and formalised in [15]. Language integration with Java is described in [14] in more depth, while its use within query languages for XML is also outlined [10, 6].

7. CONCLUSIONS

We have outlined a novel mechanism which allows XML stream queries to be decomposed into an extraction and a computation phase over the extracted data based on a single type description. While the concept requires further investigation, it has a number of advantages for some classes of application. In particular, it may allow the programmer to use a higher-level, and therefore more succinct, query without greatly affecting properties of efficiency. Queries are formulated within the domain of the host language and can thus be statically typed.

The mechanisms have been implemented and first results show some promise. However the investigation is at an early stage and a great deal of work remains to be done.
