(Dated: September 11, 2014)

In this letter we present theory and particle-in-cell simulations describing cyclotron radio emission from the Earth’s auroral region and similar phenomena in other astrophysical environments. In particular we find that the radiation, generated by a down-going electron horseshoe distribution is due to a backward-wave cyclotron maser emission process. The backward wave nature of the radiation contributes to upward refraction of the radiation that is also enhanced by a density inhomogeneity. We also show that the radiation is preferentially amplified along the auroral oval rather than transversely. The results are in agreement with recent Cluster observations.

The electron cyclotron-maser instability plays a significant role in the generation of highly non-thermal, polarised radio emission from the auroral region of planets and stars having a dipole-like magnetic field [1, 2]. More recently, this radiation model has been extended to a variety of astrophysical environments including Blazar jets, collisionless shocks and brown dwarfs [3–7]. Planetary auroral radio emission has been a topic of interest for many years with several mechanisms having been proposed [8–13, 17, 18]. As the dispersion relation describing the electromagnetic wave growth only depends on the factor by which the magnetic field increases and on the ratio of plasma and cyclotron frequencies, the mechanism can scale effectively over many orders of magnitude both in wavelength and spatial scale. Blazar jets in particular represent a prime example of this scalability [3]. Generated perpendicular to the accretion disc of super massive black holes, they can extend over many thousands of light years and have been observed to generate highly non-thermal radio emission at frequencies in the 100s of GHz range. It has been suggested that small scale magnetic mirrors or convergent flux tubes may be formed within the jet via hydrodynamic instabilities or shocks, providing the means of generating the required electron velocity distribution [3, 6]. In the Earth’s auroral region, observations by the Viking spacecraft [11, 19] and the FAST satellite [17] led to the suggestion that the free energy source for AKR is a population of downward accelerated electrons having a large perpendicular velocity produced by a combination of parallel accelerating electric fields and converging magnetic field lines. The electron distribution takes the form of a horseshoe or crescent shape due to the first adiabatic invariance as the electrons move into the stronger magnetic field. The Fast Auroral SnapshoT (FAST) satellite [13, 17, 20] clearly demonstrates a strong correlation between the electromagnetic wave emission and the occurrence of the horseshoe distribution [13]. Further observations by FAST of localised double-layer structures within the auroral density cavity have combined our understanding of auroral particle acceleration with the AKR emission process [14]. The associated formation of drifting electron and ion holes have also been presented as an explanation for striated AKR, with models of cyclotron-maser emission occurring discretely within electron holes [15] and explanations of coupling dynamics, spectral content and escape of the radiation from the electron-hole structures [16]. In all cases, the cyclotron-maser instability is presumed to be driven by an electron horseshoe or modified horseshoe-ring distribution. Scaled laboratory experiments have demonstrated the potential for such horseshoe distributions to generate narrowband cyclotron-maser emission at GHz frequencies over distances of a few meters [21–25].

Although the generation mechanism is well established, there remain important questions with regard to how the radiation may propagate within the parent au-
auroral density cavity and ultimately escape [26]. Cairns et al. [27] have demonstrated how the radiation, generated just below the electron cyclotron frequency, may successfully couple onto the upper branch of the plasma dispersion relation and escape. This model assumes near field-aligned R-mode polarisation prior to escape, as observed by the Cluster satellite mission [28]. However, it is well known that the radiation is generated near perpendicular to the magnetic field in the X-mode [20] and will undergo strong resonant absorption when the radiation encounters the second harmonic layer [26]. The absorption is maximum when the radiation propagates perpendicular to the magnetic field and goes to zero as the radiation propagates parallel to the magnetic field [10]. The manner by which the radiation may effectively be redirected along the magnetic field and ultimately escape is a question recently addressed by Mutel [28] and Meniett [29], with a model of upward refraction that is due to altitude variation in the background plasma density and an initial radiation propagation vector that is mildly against the direction of the electron flux (negative axial wavenumber), see Fig. 1. They also concluded that there was enhanced growth of the radiation tangential to the auroral oval [29]. Current theoretical models for X-mode generation via the cyclotron-maser instability do not predict growth with a negative axial wavenumber, however we have developed a new theoretical model that clearly demonstrates an enhanced growth rate for finite negative axial wavenumbers and moderate electron energy spread within a horseshoe shaped electron velocity distribution [11, 13]. This model is verified by the results of full 3D PIC (Particle-in-cell) code simulations, demonstrating for the first time that auroral cyclotron-maser emission is indeed characterised by a finite negative axial wavenumber.

The theoretical model assumes an analytic form for the electron distribution function with different pitch angles, energy spread and density ratios between the hot component making up the horseshoe element and a background Maxwellian component. This is then used in a dispersion relation for the RX mode which is obtainable from the susceptibility tensor given by Stix [30]. We assume that the frequency is close to the electron cyclotron frequency, and that the Larmor radius is much less than the wavelength for typical electron velocities. This latter condition means that we need only consider the susceptibility to lowest order in $\frac{\omega - \omega_{ce}}{\omega_{ce}}$ where $\omega_{ce} = eB/\gamma m_e$ is the relativistic electron cyclotron frequency with $e$ the electron charge, $B$ the magnetic flux density, $\gamma$ the Lorenz factor and $m_e$ the electron rest mass. If we neglect all but the zero order terms we get the cold plasma result.

To a first approximation we need only take account of the velocity distribution of the electrons in the resonant integral which involves $1/(\omega - \omega_{ce})$. In terms of momentum $p$ in the weak relativistic limit we have $\omega_{ce} \approx \omega_{ce0}(1 - p^2/2m_e^2c^2)$ where $\omega_{ce0}$ is the nonrelativistic electron cyclotron frequency. For the real part of the resonant integral we can simply take the cold plasma value.

\[\frac{1}{\omega - \omega_{ce0}}(1 - p^2/2m_e^2c^2)\]

Although this goes as $1/(\omega - \omega_{ce0})$ and appears to be near singular at the resonance, the $1/(\omega - \omega_{ce0})$ factors in the real part of the dispersion relation cancel out and it behaves quite smoothly in the vicinity of the cyclotron frequency. It is not crucial to include small corrections to the cyclotron frequency in the real part of the dispersion relation. The refractive index $n$ for the RX mode is given by $n^2 = \epsilon_\perp - \epsilon_{xy}\epsilon_\perp$ where $\epsilon_\perp$ and $\epsilon_{xy}$ are respectively the perpendicular and $x$ and $y$ dielectric tensor elements [30]. In the limit where the Larmor radius is small compared to the wavelength, the imaginary parts of all components of the dielectric tensor for near perpendicular propagation are approximately proportional to $Im(D) = \int dv_{\perp} f d\omega/\epsilon_{\perp}$ with $v_{\perp}$ determined as a function of $v_\parallel$ by the resonance condition $\omega - k_\parallel v_\parallel = \omega_{ce}$. This assumes that the relativistic factor $\gamma$ can be set equal to 1 everywhere except in the resonance condition. If we take a typical horseshoe distribution, produced from an initial Maxwellian with drift speed 0.25c and thermal velocity 0.015c subject to magnetic compression by a factor 15, the maximum growth occurs when the resonance curve is presented in figure 2a, plotted for $\omega = 0.97\omega_{ce}$ and three different values of $n_\parallel = k_\parallel c/\omega$. The key point to note is that for positive $n_\parallel$ the curve lies above the $n_\parallel = 0$ curve, while for negative $n_\parallel$ it lies below. The other relevant point is that an increase in frequency moves the whole curve downwards, starting at a lower $v_\perp$ for $v_\parallel = 0$. Combining these two pieces of information it can be seen that in order for the resonance curve to pass through the region of maximum $\partial f/\partial v_\perp$ it must have a higher frequency when $n_\parallel$ is positive than when $n_\parallel$ is zero, so that the lower starting $v_\perp$...
at $v_\parallel = 0$ compensates for the smaller downwards curvature. Conversely for negative $n_\parallel$ maximum growth is to be expected at a lower frequency.

When the frequency is chosen so that the imaginary part of the dielectric tensor is a maximum for each value of $n_\parallel$, then the imaginary part does not vary greatly for small values of $n_\parallel$, positive or negative. However, the growth rate is approximately given by $\text{Im}(\omega) = \frac{\text{Im}(D)}{\omega_p \cdot (\text{Re}(D))}$, where $D = 0$ is the dispersion relation. As a simple approximation to $D$ we just take the cold plasma result at perpendicular incidence, a reasonable approximation if $n_\parallel$ is small and the Larmor radius is small compared to the perpendicular wavelength. The value of $\partial D / \partial \omega$ as a function of frequency is shown in Figure 2b, for $\omega_p = 0.1 \omega_{ce}$. The crucial point to note is that because of the proximity to the upper hybrid resonance, where $D$ has a singularity, the gradient shows a strong increase with frequency (figure 2b). This means that the growth rate for positive $n_\parallel$ components, where $\text{Im}(D)$ is greatest at higher frequencies is suppressed, while the net growth rate for lower $n_\parallel$ components is enhanced. This is illustrated in Figure 2c,d, which shows the relative growth rates for different values of $n_\parallel$.

If we go to larger values of $\pm n_\parallel$ the value of (1) tends to decrease since the resonance curve starts to pass through the region of optimum perpendicular gradient at a more oblique angle. This is illustrated in Figure 2d where the oblique components now have $n_\parallel = \pm 0.1$. This demonstrates that the peak growth rate is for radiation at a few degrees from perpendicular in the opposite direction to beam propagation and the results are rather insensitive to the value of $\omega_p$ in the range $\omega_p \leq \omega_{ce}$. Beam spreading in velocity space tends to produce a reduced growth rate for negative $n_\parallel$ over a smaller range of angles.

We compare the theoretical analysis with the results of PIC simulations, undertaken to study the evolution of the instability. The numerical model was defined using the particle-in-cell code VORPAL [31]. The simulation geometry comprised a Cartesian gridded region with axial length of 144$\lambda_{ce}$ (where $\lambda_{ce}$ is the vacuum wavelength of radiation at the peak electron cyclotron frequency within the simulation), symmetric transverse dimensions of 5.4$\lambda_{ce}$ and perfectly-matched-layer boundaries in $x$ and $y$ to mitigate reflection and the formation of boundary resonant eigenmodes. A 20keV electron beam was injected parallel to an axial magnetic field increasing by a factor of 15 over 45$\lambda_{ce}$. The peak magnetic flux density was plateaued over the remaining 99$\lambda_{ce}$ of beam propagation path to maintain cyclotron resonance for a significant number of Larmor steps. We considered two injected Gaussian electron velocity distributions of 2% and 6% energy spread and a ratio of electron cyclotron frequency to plasma frequency of 20.

An analysis of the transverse electric field profile $E_y$ in an x-z plane (Fig. 3) for 2% and 6% energy spread reveals a well-defined and temporally modulated electromagnetic emission at an axial coordinate of 80$\lambda_{ce}$ and polarised in the X-mode with a significant negative axial wavenumber (backward-wave component). The backward wave character of emission is evidenced by an oblique wave front propagation angle with respect to the axis of the system. Factoring in the differing axial scales in $x$ and $z$, the effective backward-wave angle for 2% energy spread is $\sim 3^\circ$ from perpendicular - consistent with requirements for the aforementioned model of upward refraction of the generated radiation [29].

The analytical theory predicts that an increase in energy spread will have a marked effect on the wavevector of emission. It is evident in figure 3 that as the energy spread increases, there is indeed such a well-defined change in the wavevector. For 6% energy spread there is still a significant negative axial wavenumber to the emission, but representing a reduction in backward propagation angle to $\sim 2^\circ$ from perpendicular. This emission profile is not only indicative of a reduction in backward wave coupling with increased energy spread, but a distinct curvature can also be observed in the wavefront for 6% energy spread between $z = 56\lambda_{ce}$ and $84\lambda_{ce}$. This curvature indicates a progressive shift towards perpendicular propagation with increasing axial coordinate, showing that the transverse electron velocity spread induced via energy transfer to the wave results in the peak growth occurring for decreasing axial wavenumbers. This result is consistent with predictions of the analytical theory and has important implications for the dynamics of the horseshoe driven cyclotron maser process.

Figure 4a contains a Fourier transform of $E_y$ at time 2156$\tau_{ce}$ and an axial position of 86$\lambda_{ce}$. A single spec-
The central component is present at $\omega/\omega_{ce} = 1$, corresponding to narrowband emission at the relativistic electron cyclotron frequency. Looking at the corresponding transverse Poynting flux over a y-z plane in figure 4b, a temporal modulation to the emission is evident, with a $810t_{ce}$ lead time for significant growth of the radio frequency (RF) Poynting flux. A peak saturated output power of $P/P_{beam} = 1.25 \times 10^{-3}$ is apparent (as the space-time average is $1/2$ of the plotted peak amplitude), which integrated over the transverse dimensions of the system (factoring in the 4 enclosing Poynting flux planes) equates to an RF conversion efficiency of 0.50%.

A comparative look at the transverse Poynting flux for 6% energy spread in figure 4c reveals a significant change in temporal character, with 2% energy spread exhibiting a highly modulated profile whilst 6% yields a more stable output, with longer period temporal fluctuations and a marginally increased peak beam-wave conversion efficiency of 0.54%. In both cases however the mean output power remains relatively unchanged. It would therefore appear that as the electron energy spread is increased, not only does the wavevector of emission tend from backward-wave to near perpendicular, but the increased energy spread also leads to a more stable cyclotron-maser emission process.

Although the simulations previously outlined demonstrate the variation in emission topography as a function of energy spread, they do not account for growth of the emission over a large number of wavelengths. This effect has significant implications for the auroral magnetospheric case, where propagation tangential to the auroral cavity boundary is considered to increase the effective path length for upward refraction [28]. A 3D PiC simulation was used to study the evolution of the horseshoe-maser instability in a sheet electron beam, with a cross-section of $9\lambda_{ce} \times 0.6\lambda_{ce}$. The parameters for this simulation are consistent with those of the previous cylindrical beam simulations, although the larger beam cross-section yielded a reduction in electron number density and increased ratio of electron cyclotron frequency to plasma frequency $\omega_{ce}/\omega_{pe} = 120$. A horseshoe distribution was also defined with 6% Gaussian energy spread and a continuous, static axial magnetic field to maintain the injected sheet aspect ratio of the electron beam over the simulation length.

The observed spectral output matches that of the initial cylindrical beam simulations, with a singular spectral component at $\omega/\omega_{ce} = 1$. A contrast is encountered however in the transverse Poynting fluxes, presented over y-z and x-z planes respectively in figure 5. It is clear that across the larger transverse dimension of the sheet electron beam (y-z plane) there is a significant enhancement in output power, with a peak output of $P/P_{beam} = 1 \times 10^{-2}$ compared with $3.5 \times 10^{-3}$ for emission across the narrower beam dimension (x-z plane). The increased output power along the larger dimension of the sheet has significant implications, supporting the hypothesis of enhanced radiated power over an extended path tangential to the auroral plasma cavity boundary [28]. The net beam-wave conversion efficiency in this case is also significantly enhanced, amounting to 2.7% of the electron beam power. This demonstrates the significance of increased growth in radiation power over greater distances.

In conclusion, we have shown that the electron cyclotron-maser instability driven by a horseshoe-shaped velocity distribution has an inherently enhanced growth rate for wave propagation with finite negative $k_\parallel$ corresponding to a backward-wave propagation angle a few degrees from perpendicular. This natural backward-wave
character to the emission serves as a suitable precursor to the recently proposed model of upward refraction and field-aligned escape of terrestrial auroral kilometric radiation [28, 29]. This also limits the potential for harmonic absorption at perpendicular propagation [26]. We have also demonstrated that the wave power increases over larger path lengths. This has bearing on the currently proposed model of AKR upward refraction, where the largest path length for refraction (tangential to the auroral oval) also corresponds to the path of most efficient power output [29].
