Abstract—The rotation of rotor blades of a helicopter induces a Doppler modulation around the main Doppler shift. Such a non-stationary modulation, commonly called micro-Doppler signature, can be used to perform classification of the target. In this paper a model-based automatic helicopter classification algorithm is presented. A sparse signal model for radar return from a helicopter is developed and by means of the theory of sparse signal recovery, the characteristics parameters of the target are extracted and used for the classification. This approach does not require any learning process of a training set or adaptive processing of the received signal. Moreover, it is robust with respect to the initial position of the blades and the angle that the LOS forms with the perpendicular to the plane on which the blades lie. The proposed approach is tested on simulated and real data.

I. INTRODUCTION

The micro-Doppler (mD) effect refers to the variations of the Doppler frequency induced by micro motions of some components of a target, such as oscillations of arms and legs of a walking human or rotations of rotor blades of a helicopter. Such a variation represents an unique signature of the target which can be exploited for civil and military purposes as classification, identification and radar imaging [1], or even medical applications as rehabilitation. In the last decade several mD-based radar techniques have been presented [2].

Based on the mD features of a target, the latter can be classified. The mD features extraction is generally performed by using time-frequency analysis tools. In [3] the authors developed an mD features extraction approach which derives from the combination of the Short Time Fourier Transform (STFT) and the Wigner Distribution; in [4] the STFT was used in conjunction with the pseudo-Zernike moments in order to classify different human targets. However, these methods present a relative high computational cost due to the computation of a time-frequency distribution and depend on the choice of the parameters of the distribution itself (i.e. window length), which, in turn, depend on the dynamic of the target.

The capability to classify a helicopter by analysing its mD properties was first investigated in [5], after that in [6] was demonstrated that the theoretical return signal from propeller blades depend on the number, the length and the rotation speed of the blades themselves. Misiurewicz et al. showed that the detection/identification is possible in the time domain, even if only with a moderate probability of detection. In [7] was demonstrated that even a passive bistatic radar (PBR) is able to record the mD signature of a helicopter. An mD features extraction algorithm from helicopter return signal was presented in [8], which is still based on the computation of the STFT.

In this paper an automatic helicopter classification algorithm is presented, which does not need the computation of any time-frequency representation; thus, it is independent of the received signal, since no parameters have to be adapted to the input signal, such as the window length. Moreover, it is robust with respect to the initial position of the blades and the angle that the LOS forms with the perpendicular to the plane on which the blades lie. The proposed algorithm exploits a sparse signal recovery technique in order to estimate the mD features and automatically carry out the classification.

The remainder of the paper is organized as follows. Section II introduces the developed sparse signal model for helicopter return signals. In Section III the algorithm is described in details, while in Section IV and Section V experimental results on simulated and real data, respectively, are presented. Section VI concludes the paper.

II. SPARSE SIGNAL MODEL

Let the state vector $\zeta = (\kappa, \rho, \omega)$ represent the number, the length and the rotation speed, respectively, of the blades of the helicopter present in a range cell, which has already been detected; according to [9], the received radar signal $y(t)$ can be expressed as a superposition of the returns from each blade of the helicopter:

$$y(t) = e^{-j \frac{2\pi}{\lambda} R_0} \times$$

$$\rho \sum_{n=0}^{\kappa-1} \text{sinc} \left( \frac{4 \rho}{\lambda} \cos \beta \cos \left( 2\pi \omega t + 2\pi \frac{n}{\kappa} + \phi \right) \right) \times$$

$$e^{-j \frac{2\pi}{\lambda} \cos \beta \cos \left( 2\pi \omega t + 2\pi \frac{n}{\kappa} + \phi \right)},$$

with $t = t_0, \ldots, t_{T-1}$, where $T$ is the number of time samples, $\lambda$ is the wavelength, $\text{sinc} (\alpha) = \frac{\sin(\alpha)}{\pi \alpha}$ and $j = \sqrt{-1}$. $R_0$ is the range of the target and $\beta$ is the aspect angle, defined as the complementary of the angle formed by the line of sight and the perpendicular to the plane on which the blades of the helicopter lie. Finally, $\phi$ is a random phase which accounts for the initial position of the blades.

The idea is to express the vector $y \in \mathbb{C}^T$, which contains the slow time samples of the received signal, as:

$$y = \Psi x + e,$$

where $x \in \mathbb{C}^M$ is sparse, $\Psi \in \mathbb{C}^{T \times M}$ is called dictionary and $e \in \mathbb{C}^T$ is a noise vector, and then estimate the state vector $\zeta$.
by recovering the sparse vector $\mathbf{x}$. The sparse signal recovery problem, which is stated as follows:

$$\hat{\mathbf{x}} = \arg \min_{\mathbf{x}} \|\mathbf{x}\|_0 \text{ s.t. } \|\mathbf{y} - \Psi \mathbf{x}\|_2^2 \leq \epsilon,$$  \hfill (3)

is generally solved by means of two approaches. The first one is based on the resolution of a convex optimisation problem, obtained after replacing the $\ell_0$-norm with the $\ell_1$-norm, since the former makes (3) a highly non-convex problem; in [10] the author demonstrated that the $\ell_0$- and the $\ell_1$-minimization lead to the same solution if the result is sufficiently sparse. The second class of approaches refers to greedy algorithms, such as the Orthogonal Matching Pursuit (OMP) [11], which finds the sparse support of $\mathbf{x}$ iteratively, and then computes its values by means of a least square projection.

The sparse representation shown in (2) is obtained by discretising the state space in $M = K \times R \times O$ grid points, indicated as $\zeta(k,r,o) = (\kappa(k), \rho(r), \omega(o))$. Thus, the equation (1) can be rewritten as:

$$y(t) = e^{-j \pi \kappa(k) R t} \sum_{k(k) \in K} \sum_{\rho(r) \in R} \sum_{\omega(o) \in O} \psi_{k,r,o}(t), \hfill (4)$$

where $K$, $R$ and $O$ are sets, or alphabets, with cardinality $K$, $R$ and $O$, respectively. The function $\psi_{k,r,o}(t)$ is a generic column, or atom, of the dictionary $\Psi$, defined as:

$$\psi_{k,r,o}(t) = \rho(r) \times \sum_{n=0}^{\kappa(k)-1} \text{sinc} \left( \frac{4 \rho(r)}{\lambda} \cos \beta \cos \left( 2\pi \omega(o) t + 2\pi \frac{n}{\kappa(k)} + \phi \right) \right) \times e^{-j \pi \frac{\rho(r)}{\lambda} \cos \beta \cos \left( 2\pi \omega(o) t + 2\pi \frac{n}{\kappa(k)} + \phi \right)}.$$  \hfill (5)

The dictionary is a block matrix organised as follows:

$$\Psi = [\Psi_{K}(0,0), \ldots, \Psi_{K}(R-1,0), \Psi_{K}(0,1), \ldots, \Psi_{K}(R-1,1), \ldots, \Psi_{K}(R-1,O-1)],$$

where:

$$\Psi_{K}(r,o) = [\psi_{0,0,0}(t), \ldots, \psi_{-1,1,0}(t)].$$  \hfill (7)

Accordingly to the structure of $\Psi$, the vector $\mathbf{x}$ is organised as follows:

$$\mathbf{x} = [\mathbf{x}_K(0,0), \ldots, \mathbf{x}_K(R-1,0), \mathbf{x}_K(0,1), \ldots, \mathbf{x}_K(R-1,1), \ldots, \mathbf{x}_K(R-1,O-1)],$$

where:

$$\mathbf{x}_K(r, o) = [\mathbf{x}_{0,0,r}, \ldots, \mathbf{x}_{-1,1,r}].$$  \hfill (9)

Thus, if $\zeta(k,r,o)$ is the state vector which characterises the target, $x_{k,r,o} = 1$; $x_{k,r,o} = 0$ otherwise.

In order to make the algorithm independent of the RCS of the target, the received signal in (4) is normalized as follows:

$$\tilde{y}(t) = \frac{y(t)}{\max |y(t)|},$$

as well as the atoms in (5):

$$\tilde{\psi}_{k,r,o}(t) = \frac{\psi_{k,r,o}(t)}{\max |\psi_{k,r,o}(t)|},$$  \hfill (11)

where $|\cdot|$ indicates the absolute value. Moreover, in order to eliminate any strong return from the stationary components of the helicopter, such as the fuselage, the received signal is pre-processed by subtracting its mean.

### III. Algorithm

The algorithm described in this section for the recovery of $\mathbf{x}$, hence for the estimation of $\zeta = (\kappa, \rho, \omega)$ and the classification of the target, is a modified version of the Pruned Orthogonal Matching Pursuit (POMP) presented in [12]; the authors combined the iterative OMP algorithm with a pruning process in order to solve a parametric sparse representation problem. The proposed algorithm can be divided in three stages:

A) Synchronisation of the received signal;

B) Estimation of the state vector $\zeta$;

C) Classification.

They are presented in the following three subsections.

#### A. Synchronisation

In order to make the algorithm independent of the initial position of the blades, the instant $t_0 = 0$ is synchronised with the first flash, that is spike, of the received signal $|\tilde{y}(t)|$. Figure 1 shows an example of simulated signal received from an MD 500E Defender helicopter with SNR = −5 dB.

![Figure 1](image-url)  
**Figure 1.** Example of the magnitude of a simulated radar signal received from an MD 500E Defender helicopter with SNR = −5 dB.

The threshold $\eta$ depends on the statistical characteristics of the received signal. Assuming an additive white Gaussian noise (AWGN) scenario, $|\tilde{y}(t)|$ has a Rice probability density function (PDF). Since the tail of the PDF is due to the higher amplitude of the flashes compared to the noise, $\eta$ is computed as the 99.5% quartile of the distribution. Thus:

$$\eta = \text{arg min } |\tilde{y}(t)| \text{ s.t. } |\tilde{y}(t)| > \eta.$$  \hfill (12)

The threshold $\eta$ can be computed using the Cumulative Distribution Function (CDF) of $|\tilde{y}(t)|$. Accordingly, the atoms in (11) are synchronised by choosing $\phi = \pi/2$.

#### B. Estimation of $\zeta$

The estimation of $\zeta$ is the core of the algorithm and it is explained in this section. The letter $l$ indicates the counter; $\mathbf{r}^{(l)}(r,o)$ and $\mathbf{x}^{(l)}_K(r,o)$ are the recovery residual and the estimate of the vector $\mathbf{x}_K(r,o)$, respectively, at iteration $l$; $\mathbf{A}^{(l)}(r,o)$ is the set of selected atoms; $\mathbf{A}^{(l)}(r,o)$ is the matrix whose columns specified by the indices in $\mathbf{A}^{(l)}(r,o)$ are equal to the corresponding columns $\Psi_{K}(r,o)$, 0 elsewhere.
0) Initialization: \( l = 1, \hat{x}_K^{(0)}(r,o) = 0, r^{(0)}(r,o) = \hat{y}, \)
\( \Lambda^{(0)}(r,o) = \emptyset, \Phi^{(0)}_\Lambda(r,o) = 0. \)

1) For each couple \((r,o)\)

1.1) The inner product between the residual at the previous step, \( r^{(l-1)}(r,o) \), and the block \( \Psi_K(r,o) \) of the dictionary is carried out and stored in \( p: \)
\[
p = \left\langle \Psi_K(r,o), r^{(l-1)}(r,o) \right\rangle. \tag{14}\]

1.2) \( \hat{i} \) indicates the location of the maximum value of \( p: \)
\[
\hat{i} = \arg \max_i p(i), \tag{15}\]
which is then added to the set \( \Lambda^{(l)}(r,o): \)
\[
\Lambda^{(l)}(r,o) = \Lambda^{(l-1)}(r,o) \cup \hat{i}. \tag{16}\]

1.3) \( \Phi^{(l)}_\Lambda(r,o) \) is updated accordingly to the new set of selected atoms \( \Lambda^{(l)}(r,o) \).

1.4) The estimate of the vector \( \hat{x}_K^{(l)}(r,o) \) is performed as solution of a least square problem:
\[
\hat{x}_K^{(l)}(r,o) = \left[ \Phi^{(l)}_\Lambda(r,o)^H \Phi^{(l)}_\Lambda(r,o) \right]^{-1} \Phi^{(l)}_\Lambda(r,o)^H \hat{y}. \tag{17}\]

1.5) The residual is updated as:
\[
r^{(l)}(r,o) = \hat{y} - \Phi^{(l)}_\Lambda(r,o) \hat{x}_K^{(l)}(r,o). \tag{18}\]

2) Remove \( \left[ \frac{O}{2} \right] \) candidate values from \( \mathcal{O} \), which correspond to the largest residual error \( \|r^{(l)}(r,o)\| \), where \( \| \cdot \| \) indicates the \( \ell_2 \)-norm of the vector. At the \( l \)-th cycle, the number of couples \((r,o)\) is then \( R \times \left[ \frac{O}{2} \right] \).

3) If \( \left[ \frac{O}{2} \right] > 1 \), increment \( l \) and return to the step 1, otherwise go to step 4.

4) Since \( \mathcal{O} \) has only one value left, whose index is \( \hat{o} \), this represents the estimated angular velocity of the target, \( \hat{\omega} = \omega(\hat{o}) \). Moreover, let \( \hat{l} \) be the last value of the counter at this stage; \( \hat{\rho} \) is equal to:
\[
\hat{\rho} = \rho(\hat{r}), \tag{19}\]
where:
\[
\hat{r} = \arg \min_r \left\| r^{(l)}(r,\hat{o}) \right\|. \tag{20}\]

5) Repeat the step from 1.1) through 1.5) \( K \) times, with \( \hat{r} \) and \( \hat{o} \) in place of \( r \) and \( o \), respectively, and the following initial values: \( l = 1, \hat{x}_K^{(0)}(\hat{r},\hat{o}) = 0, r^{(0)}(\hat{r},\hat{o}) = \hat{y}, \)
\( \Lambda^{(0)}(\hat{r},\hat{o}) = \emptyset, \Phi^{(0)}_\Lambda(\hat{r},\hat{o}) = 0. \)

6) Let \( \hat{l} \) be the last value of the counter at this stage, then:
\[
\hat{k} = \kappa(\hat{l}), \tag{21}\]
where:
\[
\hat{k} = \arg \max_k \left| \hat{x}_K^{(\hat{l})} (\hat{r},\hat{o}) \right| = \arg \max_k \left| [\hat{x}_{0,\hat{r},\hat{o}}, \ldots, [\hat{x}_{K,\hat{r},\hat{o}}], \ldots, |\hat{x}_{K-1,\hat{r},\hat{o}}] \right|, \tag{22}\]
completes the estimation process.

**C. Classification**

At the end of the first two stages the state vector \( \hat{\zeta} = (\hat{k},\hat{\rho},\hat{\omega}) \) is estimated. Let \( h_0, \ldots, h_{N-1} \) be the triples which represent \( V \) known helicopters, the classification is obtained by computing a weighted Euclidian distance:
\[
\hat{v} = \arg \min_v \left\| (\hat{\zeta} - h_v)^T s \right\|, \tag{23}\]
where \( s \) is the vector of the weights.

**IV. EXPERIMENTAL RESULTS ON SIMULATED DATA**

The algorithm is tested by means of simulated data. For different values of the SNR, 90 trial radar signals with a carrier frequency of 5 GHz are generated by using the equation (1), 10 for each target listed in Table I. The initial phase \( \phi \) and the aspect angle \( \beta \) are considered unknowns and are chosen randomly, in particular the latter ranges in \([0^\circ, 70^\circ]\). The duration of the signals is chosen such that at least a complete rotation period is contained; considering the minimum product between the first and the third column, it is assumed equal to 0.25 seconds. Furthermore, it is supposed to have a system with a pulse repetition frequency (PRF) able to cope with the maximum expected Doppler shift; in this case, since:
\[
f_{mD,max} = \frac{2\pi \max (\omega \rho)}{\lambda}, \tag{24}\]
it is chosen equal to 8 kHz.

The dictionary \( \Psi \) is built by choosing the following alphabets:

<table>

<td>5.8</td>
</tr>
</tbody>
</table>

The classification is performed by computing a weighted Euclidian distance with the following weights:
\[
s = [0.25, 0.75]. \tag{28}\]
This choice is made in order to penalise the estimates of $\rho$ and $\kappa$, which are the most affected by the noise. In particular $\hat{\rho}$ is weighted by 0 because, as shown in (1), $\rho$ appears both as a real multiplicative factor and multiplied by $\cos \beta$. In the first case, the information lost since the algorithm is made independent of the RCS through (10) and (11), besides it is affected by the additive noise. In the second case, since $\beta$ is unknown, even the product $\rho \cos \beta$ is unknown, hence its estimate is not reliable. However, it has to be kept in the model in order to evaluate both $\kappa$ and $\hat{\omega}$.

The performance in terms of percentage of correct classification is shown in Figure 2. Even at $SNR = -7.5$ dB, the helicopters are correctly classified in the 72.22% of the cases. For values of the SNR above 0 dB, the percentage of correct classification is above 80%.

![Classification Performance - Simulated Data](image)

Figure 2. Performance on simulated data in terms of percentage of correct classification.

Table II shows the confusion matrix at $SNR = 0$ dB. AH-64, MI-2 and CH-53 present the highest mismatch rates. The first two are mostly confused with AH-1 and UH-60, respectively, and this is likely due to their similar rotation speeds, while the last one is confused with SA365. However, 6 out of 9 helicopters present a percentage of correct classification higher than 95%.

### Table II. Confusion Matrix: Results on Simulated Data at $SNR = 0$ dB.

V. Experimental Results on Real Data

The validity of the approach is proved with real data. Signals from the two-bladed helicopter scale model GAUI X3 are acquired with a 24 GHz Continuous Wave (CW) radar, whose sampling frequency is 22 kHz. Three rotation speeds are chosen, in order to simulate as many targets A, B and C; their actual values are not available, hence they are evaluated by inspection of the time domain signals and the obtained values are shown in Table III, along with the standard deviations of the estimates. The database which contains the parameters of the helicopters to classify is shown in Table IV; targets from D to L present either equal rotation speeds but different number of blades or the same number of blades with similar rotation speeds of the true targets A, B and C, in order to test the reliability of the algorithm. Accordingly to this choice, the dictionary $\Psi$ is designed with the following alphabets:

$$K = \{2, 3, 4\}, \quad \beta \in \{0.30, 0.31, \ldots, 0.40\}, \quad O = \{6.50, 6.51, 6.52, \ldots, 13\}.$$ (29) (30) (31)

Without loss of generality, a non-uniform sampling strategy is used for the alphabet $O$, denser in the neighbourhood of the expected values. As before, $\beta$ is 70°, $R_0$ is $\lambda/16$ and the weight vector $s$ is chosen equal to (28). With these values, the signal length and the sampling frequency are chosen equal to 0.4 seconds and 5.5 kHz, respectively.

### Table III. Scale Model’s Rotation Speed

<table>
<thead>
<tr>
<th>Target</th>
<th>Actual Speed</th>
<th>Standard Deviation</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>6.72 rps</td>
<td>0.07</td>
</tr>
<tr>
<td>B</td>
<td>9.12 rps</td>
<td>0.05</td>
</tr>
<tr>
<td>C</td>
<td>12.42 rps</td>
<td>0.15</td>
</tr>
</tbody>
</table>

Three acquisitions are made for each speed, at three different aspect angles $\beta$. From each signal, whose total length is 20 seconds, 50 segments of 0.4 seconds are extracted and downsamplied with a factor of 4 in order to match the sampling frequency of 5.5 kHz.

The performance is shown in Table V in terms of percentage of correct classification. For $\beta = 0^\circ$ the performance is lower than the other two cases because of the small RCS of the blades; however, this is an unlikely scenario since it means that the helicopter is flying at the same altitude of the radar. For values of $\beta$ equal to 30° and 60°, the correct classification is 100% for A and B, and above 80% for C; this dissimilarity is due to the higher fluctuation that C’s rotation speed presents, as shown in Table III.

VI. Conclusion

In this paper a novel model-based automatic classification algorithm for helicopters was presented. A sparse signal model for radar return from a helicopter was designed and used in conjunction with a greedy sparse signal recovery algorithm to extract the micro-Doppler parameters of the target. The latter were then used to perform the classification by simply comparing them with micro-Doppler parameters of known helicopters. Unlike other approaches, the proposed algorithm does not need the computation of any time-frequency distribution, which makes it independent of the dynamic of the received signal, and presents a low computational cost since the dictionary can be pre-computed based on the database of expected targets. Moreover, this method is independent of both the initial position of the blades and the inclination of the helicopter with respect to the LOS. The algorithm was tested by using both simulated and real data. The experimental results on simulated data show the capability of the algorithm of classifying the targets independently of both the initial phase of the signal and the aspect angle. The results obtained on real data confirm the validity of the approach, leading to an average 96% of correct classification in the cases of most interest.
