An output coupler for a W-band high power wideband gyro-amplifier

Paul McElhinney, Craig R. Donaldson, Johannes E. McKay, Liang Zhang, Duncan A. Robertson, Member IEEE, Robert I. Hunter, Graham M. Smith, Wenlong He and Adrian W. Cross

Abstract—An output coupler for a W-band high power wideband gyro-amplifier has been designed, manufactured and experimentally measured. It consists of a high performance sin²-parallell corrugated horn integrated with a broadband multi-layer window. The major design requirements are that the horn/window combination must have an input return loss lower than -30 dB over a 10 GHz bandwidth, provide a high quality output beam pattern, and operate under ultra-high vacuum conditions. The coupler converts a circular waveguide TE₁₁ mode into the free space Laguerre Gaussian LG₀₀ mode over the frequency band of 90–100 GHz with a measured return loss of between -30 and -40 dB and a simulated Gaussian coupling efficiency of over 99% at 94 GHz.

Index Terms—corrugated horn, Gaussian coupling, microwave window

I. INTRODUCTION

Gyro-devices [1-3] are well suited to applications in plasma physics, remote sensing, radar, high-field electron paramagnetic resonance and dynamic nuclear polarization for Nuclear Magnetic Resonance due to their capability to produce high power coherent radiation at high frequencies in the millimeter and sub-millimeter range. A W-band gyrotronbackward wave oscillator (gyro-BWO) [4] and gyrotron traveling wave amplifier (gyro-TWA) based on a cusp electron beam source [5, 6] have been developed to provide a wideband tunable source with an output power of ~10 kW and ~5 kW, respectively. The gyro-TWA is designed to amplify a 1 W signal, injected through an input coupler [7, 8], to a power of ~5 kW over the frequency range of 90-100 GHz. The gyro-TWA uses a helically corrugated interaction region to allow high power amplification over a broadband frequency range. The input and output mode of the interaction region is a circularly polarized TE₁₁ mode whilst the interaction is at the 2nd harmonic of the electron cyclotron frequency. The amplified signal is then output though a corrugated horn [9] and a multi-layer vacuum window [10, 11] to provide a high purity Gaussian beam, suitable for many applications.

The output coupler needs to operate under ultra-high vacuum (UHV) conditions and ideally have a reflection coefficient of less than -30 dB across the 10 GHz bandwidth of the amplifier to avoid the possibility of parasitic oscillations. For most applications it is also desirable for the output beam to have as low sidelobes as possible to minimize uncoupled or scattered power.

Previously, the horn and window were designed and manufactured as separate components. The original corrugated horn [9] had a 105 mm long sin² profile over which the corrugation depth tapered linearly from -\(\lambda/2\) to \(\lambda/4\) to minimize the reflection over the operational bandwidth. The input and output radii were 2.8 and 13.0 mm respectively. That horn achieved an input reflection coefficient of better than -30 dB over a 10 GHz bandwidth, a Gaussian coupling efficiency of 98% at band center, and sidelobe levels at -25 dB. The original window [10, 11] used a 3-disk multi-layer configuration in which performance was optimized when the phase front of the incident beam was planar at the vacuum window and field components were kept away from the edges of the window. That horn and window combination achieved an input return loss of better than -27 dB over 90-100 GHz.

This work describes a new integrated horn and window output coupler, designed to interface with a quasi-optical transmission line suitable for integration into radar or magnetic resonance spectroscopy applications. The new design aims to achieve higher performance by combining HE₁₁ modes in phase at the aperture [12]. The primary objectives were to maximize the Gaussian coupling and reduce the sidelobe levels, to maximize power delivery to the application and minimize scattered power, whilst maintaining the low input return loss to ensure amplifier stability with high gain interaction regions, within a vacuum compatible construction.

In this paper, the design, manufacture and measurement of the new UHV-compatible integrated corrugated horn and window are presented.

II. SIMULATION AND OPTIMIZATION OF THE HORN AND WINDOW

The corrugated horn antenna has been extensively studied and reported by Clarricoats [13] for radar and communications applications. The corrugated horn primarily converts the TE₁₁ input waveguide mode into the HE₁₁ corrugated horn mode, which has an aperture electric field distribution of the form given by Eq. 1.
\[ E_r(r) = J_0 \left( \frac{2.405 \, r}{a_0} \right) \]  

where \( a_0 \) is the radius of the aperture, \( r \) is the radius and \( J_0 \) is the zeroth order Bessel function of the first kind. This aperture field is close to a Gaussian field distribution and it has been shown that a pure HE\(_{11} \) mode will couple with 98\% efficiency to a fundamental Laguerre Gaussian LG\(_{00} \) beam with a beam waist \( w_0 = 0.644/a_0 \) situated at the aperture [14, 15].

In practice any corrugated horn taper will also excite higher order HE\(_{1m} \) modes and in particular the HE\(_{12} \) mode. The relative magnitude and phasing of this mode, with respect to the HE\(_{11} \) mode, is the main factor that determines the amplitude and effective radius of curvature of the field at the aperture [16]. This in turn determines the coupling coefficients to any given orthonormal Gaussian mode beam set, specified by a fundamental beam radius \( \omega \) and radius of curvature \( R \), at the aperture.

It can be shown to a good approximation that coupling to a fundamental Gaussian beam, with a planar wavefront, is maximized when the HE\(_{12} \) mode is in phase with the HE\(_{11} \) mode and the respective amplitude levels are approximately 0.2 and 0.98 [12]. For this particular case the beam waist will be situated close to the aperture with a radius \( w_0 \approx 0.57a_0 \).

The profile of the new horn, consists of a \( \sin^2 \) corrugated profile to excite the desired HE\(_{12} \) amplitude, followed by a straight corrugated phasing section to bring the modes into phase at the aperture, a design which has been described previously [12, 18]. The \( \sin^2 \) profile can be described by Eq. 2

\[ r(z) = r_{in} + (r_{out} - r_{in}) \left[ \frac{Z}{L} \left( 1 - A \right) + A \sin^2 \left( \frac{\pi z}{2L} \right) \right] \]  

where \( L \), \( r_{in} \) and \( r_{out} \) are the length, the input and output radius of the profiled section. The value of \( A \) approximately determines how much of the HE\(_{12} \) mode is excited [12].

Simulations show that a value of \( A \approx 0.7 \) excites the desired 0.2 HE\(_{12} \) amplitude (4\% power) and leads to respective lengths for the \( \sin^2 \) profile and linear phasing section of:

\[ L_{horn} = L_{profile} + L_{phase} \]

\[ = \frac{2.4a_0^2}{\lambda_0} + \frac{2a_0^2}{\lambda_0} \]

where \( \lambda_0 \) is the free space wavelength at the desired frequency \( f_0 \) and \( a_0 \) is the output aperture radius. The input radius \( r_{in} \) of 1.45 mm matches that of the output radius of the gyro-TWA interaction region. The output radius \( r_{out} \) of 12.5 mm was chosen for practical reasons relating to fragility of the window components and keeping the horn length reasonable. From these values it is possible to derive an approximate initial length of the profiled section and that of the phase matching section using Eq. 3.

The design of the throat of the horn was optimized to minimize the input return loss. The depth of the input corrugations was tapered from close to the nominal \( \lambda/2 \) value to \( \lambda/4 \) over an impedance matching section of 20 corrugations.

The structures of the corrugated horn, the phase matching section and the window are rotationally symmetric, making mode matching analysis particularly suitable. Initially, both CORRUG [18] and \( \mu \)-wave Wizard [19] were used to calculate scattering parameters and aperture fields of the horn alone from which far-field patterns and coupling coefficients to the desired Gaussian mode set could be calculated. Both programs gave equivalent results.

Once the initial baseline design of the horn was defined, \( \mu \)-wave Wizard was used for optimization of the full structure including the window components as it is capable of simulating dielectric sections which is not possible with CORRUG. The optimization parameters were the phase matching section length \( L_{phase} \) and the impedance matching corrugation depths as well as the dimensions of the multilayer window sections.

![Fig. 1. Schematic of the horn/window assembly. Quartz disks (a), ceramic disk (b), retaining rings (c), copper rings (d) and corrugation gaps (e) and vanes (f).](image-url)
(a)-(d). Finally, the whole structure was simulated in CST Microwave Studio [20] which confirmed the mode-matching predictions.

The resulting design is predicted to have a beam waist at the aperture of \( \omega_0 = 6.81 \text{ mm} \) or \( 0.54a_0 \). The coupling between the aperture field and the fundamental Gaussian free-space mode was calculated to be 99.4% at 94 GHz, 99.2% at 90 GHz and 98.5% at 100 GHz. These values are close to the theoretical maximum obtainable of 99.6% for \( \omega_0 \approx 0.57a_0 \) [12].

### III. Construction and Assembly

The construction of the horn was carried out by Thomas Keating Ltd. using an electroforming process. During this stage, two ultra-high vacuum flanges are attached to the horn by growing copper over the spigot flanges to form a tight seal. The aluminum is then dissolved leaving the finished horn. The window consists of an alumina disk that is vacuum brazed into a titanium jacket that contains the knife edge to seal the vacuum. This assembly sits inside a stainless ring with through holes to connect to the corrugated horn. Fig. 2 shows a photograph of the finished horn and the window assembly. The total length of the horn and window is 233.8 mm.

![Photo of the constructed horn and window assembly.](image1)

The soft copper spacing rings that are between each quartz disk, and the central alumina disk allow for fine tuning of the window to compensate for manufacturing tolerances of the components as well as environmental conditions, which may induce a deviation from the ideal simulated design. The adjustment is carried out whilst measuring the return loss on a vector network analyzer (VNA): the scattering parameters can be fine-tuned to match those of the simulations. The final assembly was leak tested and was able to hold the vacuum to \( 10^{-9} \text{ mbar} \).

### IV. Experimental Results

Reflection and far- and near-field antenna measurements of the horn prototype were measured using a W-band VNA (Anritsu ME7808B). In order to measure the reflection of the horn and horn-window assembly a rectangular-to-circular converter and a circular taper were used to connect an output port of the VNA to the horn. A quick planar near field scan was also carried out using a WR-10 waveguide probe which was mounted on the second port of the VNA and scanned across the aperture of the horn with the window in place at a distance of 10 mm from the aperture. The transmission coefficient \( S_{21} \) was recorded. Fig. 5 shows the normalized aperture field intensity from the measurement. It should be noted this measurement was not

![Microwave reflection measurement and simulation of the corrugated horn with and without the window in place.](image2)

Far-field radiation measurements of the co-polar E-plane, H-plane and the cross-polar D-plane components were also carried out at 94 GHz, with the window in place, and are shown in Fig. 4. Low sidelobe levels of -35 dB are in excellent agreement with simulations of the horn alone and demonstrate that the addition of the window has a negligible effect on the antenna pattern. The cross-polar measurement is also in good agreement with the simulations, with a maximum of -31.8 dB, compared to a simulated maximum of -34.2 dB.

![The measured and simulated co-polar E-plane, H-plane and cross-polar D-plane scans of the output coupler with window at 94 GHz.](image3)
refined. It is believed that standing waves between the window and the measurement probe and surrounding hardware are the cause of the intensity fluctuations in the measurement which degrade the beam symmetry.

V. CONCLUSIONS

Using a mixture of analytical and computational methods, we have shown it is possible to design and construct an output coupler, comprising an integrated horn and a multi-layer window, which is capable of being incorporated into a wideband gyro-TWA operating under UHV conditions. The excellent agreement between simulation and the experimentally measured far field pattern indicates that the window has not created new modes within the antenna. The predicted Gaussian coupling efficiency is 99.4% and low sidelobe levels of -35 dB were measured at 94 GHz. The input reflection is less than -30 dB at 94 GHz. The output coupler holds vacuum to 10-9 mbar. This performance represents a significant improvement over previous designs and means the new output coupler is suitable for its intended use in a wideband, high power gyro-TWA, relevant for applications in radar and magnetic resonance spectroscopy.

ACKNOWLEDGEMENT

The authors thank Dr Richard Wylde of Thomas Keating Ltd. for electroforming the horn and grafting on the UHV flanges.
