Abstract

Over the last 10-15 years a new field of 'biogeotechnics' has emerged as geotechnical engineers seek to find ground improvement technologies which have the potential to be lower carbon, more ecologically friendly and more cost-effective than existing practices. This review summarizes the developments which have occurred in this new field, outlining in particular the microbial processes which have been shown to be most promising for altering the hydraulic and mechanical responses of soils and rocks. Much of the research effort in this new field has been focused on microbially induced carbonate precipitation via ureolysis (MICP); while a comprehensive review of MICP is presented here, the developments which have been made regarding other microbial processes, including microbially induced carbonate precipitation via generation are also presented. Furthermore, this review outlines a new area of study: the potential deployment of fungi in geotechnical applications which has until now been unexplored.

Microbially induced carbonate precipitation, Ureolysis, Denitrification, Biogenic gas formation, Bacteria, Fungi, Geotechnical Engineering

1 **1. INTRODUCTION**

2 Geotechnical engineers are concerned with the engineering performance of the 3 ground comprising soil, rock and the fluids (generally air or water) held within their 4 pore space or voids. As such geotechnical engineers consider the behavior of the 5 ground in terms of strength and stiffness in order to assess its performance in response 6 to loading and unloading, which may be induced at the surface or at depth. 7 Furthermore the ground acts as a source of material for use as fill, for example in the 8 construction of embankments. Often there is a need to control the flow of water into 9 or around structures to maintain stability and/or to ensure underground structures 10 remain operational (e.g. tunnels); thus we are also concerned with the hydraulic 11 behavior of the ground (e.g. permeability). In many instances the soil/rock available at 12 a given site is not adequate in terms of engineering performance for the intended 13 geotechnical application; ground improvement strategies are then employed to alter 14 the hydraulic and/or mechanical behavior.

15 Conventional ground improvement techniques are highly invasive (e.g. jet 16 grouting, permeation grouting, the formation of soil-cement/lime piles), are frequently 17 energy intensive (e.g. compaction, vibration, heating, freezing, electro-osmosis) and 18 often require the introduction of environmentally damaging chemicals or carbon-19 intensive materials into the subsurface (e.g. chemical grouts, cement). Cement 20 production alone is estimated to contribute 5-7% of total global CO₂ emissions 21 (Benhelal et al., 2013). Many countries worldwide have ambitious targets to reduce 22 their carbon emissions, for example the UK has a target to reduce carbon emissions 23 by 80% (against the 1990 baseline) by 2050. These targets present both challenges 24 and tremendous opportunities for the construction sector in the transition towards 25 low-carbon economies, as the use of cementitious materials is pervasive in conventional ground improvement techniques. There is a clear need to widen our
scope of ground improvement technologies to include lower carbon, less invasive,
less energy demanding and more environmentally-friendly practices. One potential
avenue for achieving this is to consider the role of microbial processes in soils and
rocks.

Estimates suggest that there are 2×10^9 prokaryotes (archaea and bacteria) in a 31 32 gram of soil sampled from surface (top 1m), decreasing to 1×10^8 prokaryotes at 1-8m depth in soil (Whitman et al., 1998, Gans et al., 2005). Even at greater depth 33 prokaryotes are found in abundance, with 2.3×10^7 cells/cm³ estimated to exist in 34 subsurface sediments from 10-300m, reducing to 6×10^6 cells/cm³ between 300-500m 35 36 (Whitman et al., 1998). In terms of bacterial diversity, estimates range from 6,400-37 830,000 different bacterial species per gram of soil (Curtis et al., 2002, Gans et al., 38 2005). These estimates do not include the presence or diversity of eukarya (algae, 39 fungi, protozoa). Despite the abundance and diversity of microorganisms in the 40 ground and their ability to survive/thrive in extreme environments (e.g. Dong et al., 41 2008) geotechnical engineers until recently have largely ignored their presence, 42 preferring to view the ground as a sterile engineering material.

43 In 2005, Mitchell and Santamarina published a seminal article outlining 44 biological considerations in geotechnical engineering (Mitchell & Santamarina, 45 2005). This hailed the beginning of the emergence of a new sub-discipline of 46 'biogeotechnics'. Since then research in this area has proceeded at pace with the role 47 of microbial processes in geotechnical engineering capturing the attention of many 48 research groups across the world and regular symposia and conference sessions 49 dedicated to the theme, e.g. Géotechnique Symposium in Print in 2013 on 'Bio- and 50 chemo-mechanical processes in geotechnical engineering'. Further highlighting the

51 importance of this field, the National Science Foundation in the US awarded
52 \$18.5million in 2015 to establish the Center for Bio-mediated and Bio-inspired
53 Geotechnics, led by Arizona State University.

54 This review seeks to present the developments which have occurred over the last 55 10-15 years, outlining in particular the processes which have been shown to be most 56 promising for altering the hydraulic and mechanical responses of soils and rocks. 57 Much of the research effort in this new field of biogeotechnics has been focused on 58 microbially induced carbonate precipitation via ureolysis (MICP); while a 59 comprehensive review of MICP is presented here, the developments which have been 60 made regarding other microbial processes, including microbially induced carbonate 61 precipitation via denitrification and biogenic gas generation are also presented. 62 Furthermore, this review outlines a new area of study: the potential deployment of 63 fungi in geotechnical applications which has until now been unexplored. The 64 processes outlined herein underpin the development of nature-inspired ground 65 improvement technologies, which have the potential to be more ecologically friendly 66 and cost-effective, for the construction and maintenance of resilient infrastructure.

67

68

69 2. NATURAL MICROBIAL ACTIVITY

Although the main focus of this review is to present microbial applications which could be deployed in ground engineering, geotechnical engineers should also be aware of natural microbial activity. This section outlines (in brief) two main points: (i) the role of microorganisms in soil formation and structure and (ii) the negative impacts that have been attributed to microbial activity in a number of case histories.

75

76 **2.1 Role in soil formation and structure**

77 The perspective of soil as a sterile material not only ignores the presence of 78 microrganisms in the ground but also the role that they play in soils and rocks. Indeed 79 clay scientists and geomicrobiologists now widely acknowledge the important role 80 microorganisms play in weathering processes and in the dissolution, transformation 81 and formation of clay minerals (e.g. Barker & Banfield, 1996; Douglas & Beveridge, 82 1998; Konhauser & Urrutia, 1999; Konhauser, 2007; Gadd, 2007, 2010, 2017; 83 Mueller, 2015; Cuadros, 2017). A typical pattern for microbially influenced 84 mineralisation, (not considering metabolic processes), involves metal cations in 85 solution interacting with charged groups on cell surfaces, with these sites lowering the 86 interfacial energy required for heterogeneous nucleation to occur. If the local solution 87 is supersaturated with respect to the metal cations then this results in nucleation and 88 precipitation, with the available counterions (depending on the local geochemical 89 environment) determining the final mineral phase (e.g. carbonate, phosphate, silicate 90 etc., Douglas & Beveridge, 1998, Konhauser, 2007). Many studies have shown the 91 close association or synthesis of low crystallinity or amorphous clay phases in the 92 presence of microorganisms or microbial products (both bacterial and fungal species) 93 (e.g. Barker & Banfield, 1996, 1998; Konhauser & Urrutia, 1999; Bontognali et al., 94 2014, Tazaki, 2006; 2013). Clay formation has been shown to occur even in low 95 nutrient, high salinity experiments designed to simulate deep, subsurface hard rock 96 environments (Tuck et al., 2006). Aside from their role in clay formation, 97 microorganisms also interact with clay particles such that clay particles adhere to cell 98 surfaces and bacterial exudates (e.g. polysaccharides) bind particles inducing 99 aggregation, influencing clay fabric, they also intrude into clay pores affecting 100 swelling and shrinkage behavior (Dorioz et al., 1993; Mueller, 2015). Fungi influence

soil aggregation via a number of different mechanisms, this is discussed in more detailin section 3.4.2.

103

104 **2.2 Problematic effects of microbial activity**

105 Until the emergence of 'biogeotechnics' as a field of study, there was 106 relatively little mention of microbial processes within the geotechnical engineering 107 literature, except in rare cases where microbial activity was highlighted as a 108 contributing factor to problematic effects arising on site. Such case histories have 109 been reported by Mitchell & Soga (2005), Mitchell & Santamarina, (2005), Soga & 110 Jefferis, (2008) and Jefferis (2013). Negative impacts of microbial activity have been 111 related to the oxidizing or reducing behavior of bacteria, involved in for example, the oxidation of soluble Fe^{2+} to Fe^{3+} resulting in precipitation termed as 'biofouling' or 112 113 'bioslime', this is known to contribute to clogging of groundwater wells (Jefferis, 2013). 114

115 In an extreme case, during the construction of the Carsington Dam in England 116 in the 1980s, the reaction of sulfuric acid (arising from pyrite oxidation) with 117 limestone contained in a drainage blanket, resulted in the precipitation of gypsum, 118 iron hydroxide and release of CO₂ (Mitchell & Soga, 2005; Mitchell & Santamarina, 119 2005). The former products resulted in clogging of the drainage blanket, whereas the 120 latter had a more catastrophic consequence; leading to the death of four men by 121 asphyxiation, where CO₂ had accumulated in an inspection chamber (Mitchell & 122 Soga, 2005; Mitchell & Santamarina, 2005). Cripps et al. (1993) hypothesized that 123 bacteria greatly accelerated the rate of pyrite oxidation (Mitchell & Soga, 2005; 124 Mitchell & Santamarina, 2005).

125 Furthermore, it has long been recognized that the accumulation of biomass and 126 growth of biofilms in the subsurface, often referred to as 'bioclogging' can lower soil 127 hydraulic conductivity (Slichter, 1905). Bioclogging can be problematic particularly 128 in filters, drains and geotextiles, for example in landfill barrier systems (e.g. Baveye 129 et al., 2008; Rowe, 2005; Ivanov & Chu, 2008), and efforts have typically focused on 130 minimizing microbial growth. More recently engineers are considering that 131 bioclogging could be beneficial in some applications and have attempted to reduce 132 hydraulic conductivity by enhancing microbial growth in the laboratory (Seki et al., 133 1998, 2005) and in the field (e.g. McConkey, 1990; Blauw et al., 2009; Lambert et al., 134 2010). Engineered bioclogging is not discussed in more detail in this article; readers 135 are referred to the review papers by Mitchell & Santamarina, (2005) Ivanov & Chu, 136 (2008) and DeJong et al., (2013).

137 As geotechnical engineers now begin to engage with, consider and explore a 138 wide range of microbial processes there are tremendous opportunities for: (a) 139 developing a better understanding of how microorganisms may contribute to soil 140 formation, structure and engineering behavior in a range of environments, (b) 141 investigating how microorganisms may influence the construction, operation and 142 maintenance of geotechnical structures taking into account site specific geology, 143 geochemical conditions and mineralogy and (c) understanding how particular 144 processes can be controlled and deployed to bring about hydro-mechanical alterations 145 in the ground. The following sections focus on the research conducted to-date for a 146 range of microbial processes being considered for deployment in geotechnical 147 engineering.

148

150 **3. ENGINEERED MICROBIAL ACTIVITY**

151 **3.1 Microbially induced carbonate precipitation via ureolysis**

152 **3.1.1 Process**

153 A significant proportion of carbonates found at the Earth's surface are thought 154 to be of biogenic origin (Gadd, 2010). Microbially induced carbonate precipitation is 155 a common biogeochemical process, which can occur via a number of different 156 microbial pathways including photosynthesis, ureolysis, denitrification, 157 ammonification, sulphate reduction and methane oxidation (Zhu & Dittrich, 2016). To 158 date most of the studies investigating MICP for ground engineering applications have 159 utilised ureolytic bacteria due to the relatively short times required to precipitate 160 CaCO₃ and the large masses of CaCO₃ that can be precipitated due to the high 161 solubility of the substrates in solution (urea and CaCl₂) (Van Paassen et al., 2010).

162 MICP via ureolysis relies on a bacterium hydrolyzing urea into ammonia and 163 carbonic acid (Equation 1). This is followed by the production of ammonium ions and 164 an increase in the pH surrounding the bacterial cell, due to the net production of OH⁻ 165 ions (Equation 2). As the pH increases, carbonic acid (H₂CO₃) is converted to bicarbonate ions (HCO₃⁻) (Equation 3), subsequently forming carbonate ions (CO₃²⁻) 166 167 (Equation 4). Calcium ions in solution interact with charged surfaces on the bacterial 168 cell surface and the increase in pH promotes the subsequent precipitation of calcium 169 carbonate (CaCO₃) (Equation 6) [Ferris et al., 1992; 1996; Mitchell et al., 2010]. 170 Figure 1. shows calcite crystals produced via ureolysis, with visible indentations 171 indicating that S. Pasteurii cells are encapsulated by the precipitation of calcite.

$$\operatorname{Ca}^{2^+} + \operatorname{CO}_3^{2^-} \longrightarrow \operatorname{CaCO}_3(s)$$
 (3)

176 MICP has been investigated for a wide range of applications including solid-177 phase capture of contaminants (e.g. Fujita et al., 2008), for building restoration (e.g. 178 De Muynck et al., 2010) and concrete remediation (e.g. Bang et al., 2001; Van 179 Tittelboom et al., 2010). The review presented here is only intended to cover its use in 180 ground engineering applications. From this perspective it has been investigated, over 181 the last two decades by numerous researchers from different backgrounds and with 182 different objectives (in terms of end-state) leading to a substantial body of literature 183 and a collection of varying experimental procedures.

184 Prior reviews have summarized the practical applications of MICP (often with 185 a focus on soil stabilization), field scale testing that has been carried out to date, as 186 well as the challenges and limitations of the technique (Anbu et al., 2016; DeJong et 187 al., 2010; DeJong et al., 2013; Mujah et al., 2017; Philipps et al., 2013; Umar et al., 188 2016; Wang et al., 2017). This review aims to add to the body of knowledge by 189 examining the experimental conditions, control parameters and injection strategies 190 employed in MICP by urea hydrolysis; and comparing this to reported outcomes 191 including for increases in compressive strength, decreases in permeability or 192 erodibility, and uniformity of treatment.

193

194 **3.1.2** Applications in geotechnical engineering

195 Soil stabilization

Investigation of the use of MICP via ureolysis has been widely studied for soil
stabilisation, in particular for its ability to improve compressive strength, shear
strength and stiffness, in particular in granular soils (i.e. sands and gravels) (e.g.
DeJong et al., 2006; Whiffin et al., 2007, Van Paassen et al., 2010; Al Qabany &

200 Soga, 2013). Figure 2. shows that treatment with MICP via ureolysis transforms an 201 initially loose fine sand into a cemented sand/sandstone. Treatment of sands via MICP 202 has resulted in increases in unconfined compressive strength of greater than three 203 orders of magnitude (e.g. Al Qabany & Soga, 2013) and in some cases even over four 204 orders of magnitude (Van Paassen et al., 2010 and Terzis & Laloui, 2018). As a result 205 of the increase in strength and stiffness afforded by MICP it has also been proposed 206 for settlement reduction (Martinez & DeJong, 2009) and enhancing liquefaction 207 resistance (Montova et al., 2013). Studies investigating soil stabilisation applications have been widely reported in MICP review papers (Anbu et al., 2016; DeJong et al., 208 209 2010; DeJong et al., 2013; Mujah et al., 2017; Philipps et al., 2013; Umar et al., 2016; 210 Wang et al., 2017).

211

212 *Erosion resistance*

213 MICP via ureolysis has been investigated as a method for reducing soil 214 erosion by creating a denser layer of CaCO₃ at the soil surface that is more resistant to 215 shear stresses imposed by wind or water, thereby protecting the underlying soil 216 (Figure 3). Both Gomez et al. (2015) Hamdan & Kavazanjian (2016) investigated 217 carbonate precipitation via urea hydrolysis as a means of suppressing dust generated 218 by wind erosion. Gomez et al. (2015) utilised S. pasteurii, whereas Hamdan & 219 Kavazanjian (2016) used the plant-based Jack bean urease enzyme. In both cases, 220 treated soils exhibited enhanced erosion determined either via jet impingement tests 221 (Gomez et al., 2015) or in wind tunnel tests, where the wind speed required to initiate 222 erosion in treated soils exceeded that of the control samples (Hamdan & Kavazanjian, 223 2016).

224 Studies have also demonstrated the potential of MICP via ureolysis to reduce 225 water-induced erosion, including for embankments and slopes in riverine and 226 coastal/estuarine environments and as a means of mitigating against scour around 227 bridge piers (Salifu et al., 2016; Amin et al., 2017; Bao et al., 2017). Results for all 228 studies showed increased erosion resistance of MICP treated soils, with MICP treated 229 slopes maintaining steep profiles (e.g. 53°) whereas untreated slopes exhibited 230 collapse when subjected to repeated raising and lowering of water levels (simulating 231 tidal cycles) (Salifu et al., 2016). In the case of scouring, although the treated sand 232 directly around the pier showed enhanced erosion resistance, the bridge pier was still 233 vulnerable to erosion due to undermining of the surrounding untreated sand (Bao et al. 234 2017).

235

236 Permeability reduction in porous media

237 The precipitation of microbially induced carbonate at particle contacts and on 238 grain surfaces reduces pore throat diameters and overall porosity, thus reducing 239 permeability. Sand columns treated with MICP have been shown to achieve as much 240 as 90-100% reduction in permeability from initial values (Gollapudi et al., 1995, 241 Tobler et al., 2012). Similarly MICP can be used to reduce permeability in porous 242 rock, e.g. sandstone (Tobler et al. in review). Although reduction in permeability may 243 be the target end-state, a homogeneous distribution of calcite is desirable, since a non-244 homogenous distribution with more calcite precipitated close to the injection point 245 will result in a low permeability, but from a practical perspective will result in 246 clogging around the injection well cutting off further soil/rock volumes from potential 247 treatment (Tobler et al., 2012).

248

249 *Rock fracture sealing*

250 Rock fracture grouting using MICP has received considerably less attention 251 than soil stabilization. Initial work was carried out by Zhong & Islam (1995) with the 252 motivation of enhancing hydrocarbon production by plugging fractures. They found 253 that no plugging occurred in granite cores with artificially cut fractures unless the 254 fractures contained filling material such as sand, silica fume or limestone dust. Stoner 255 et al. (2005) used micromodels to investigate flow in fractures with realistic surface 256 roughness and found that, under constant flowing conditions, vein-like flow paths 257 formed due to MICP.

258 El Mountassir et al. (2014) sealed lab-scale artificial fractures consisting of 259 polycarbonate surfaces. In these experiments flocculation of the bacteria was induced 260 in order to aid settling and straining of the bacteria in the fractures. They found that, 261 for all flow velocities tested, preferential flow paths would form when MICP was 262 carried out with constant flow rate injections and no static periods. This was thought 263 to occur due to shear stresses on the fracture surfaces exceeding the bacterial 264 attachment threshold; they found that by reducing injection flow rates it was possible 265 to fill in the preferential flow paths. Using a similar injection strategy (although with 266 no induced flocculation), Minto et al. (2016) found that, in a large-scale artificial granite fracture with radial injection, relatively uniform precipitation could be 267 obtained over an area at least $3.1m^2$ and that high flow velocity could be used to limit 268 269 bacterial attachment and CaCO₃ precipitation in the vicinity of the well. Minto et al. 270 (2016) achieved a reduction in fracture transmissivity of three orders of magnitude in 271 3 treatment cycles.

Cuthbert et al. (2013) carried out a field trial in which a single fracture inDacite rock was sealed with eight MICP treatment cycles over four days. Two

adjacent monitoring boreholes were used for cross-hole conductance testing before and after MICP. To encourage flocculation of bacteria and attachment within the fracture, the bacteria was first mixed with 0.2M CaCl2 and then injected simultaneously with urea through a separate injection line. They inferred a reduction in fracture transmissivity of 99% close to the injection well, and 33% at a distance of 2m from the injection well via cross-hole conductance tests.

280 Only one study has to date been carried out on the mechanical behavior of 281 MICP grouted fractures. Tobler et al., (in review) sealed four artificial fractures cut in 282 38 mm diameter granite cores. One core was thin sectioned for optical and SEM 283 analysis whilst the remaining three were non-destructively scanned with X-ray 284 computed tomography then shear strength was measured. Both SEM and X-CT 285 revealed CaCO₃ covering most of both top and bottom fracture surfaces and, in 286 places, entirely bridging the gap between surfaces. All sheared samples showed a 287 higher residual resistance to shear than the uncemented rock surface and peak shear 288 strength was found to correlate with the area of CaCO₃ bridging across the two 289 fracture surfaces.

Fracture sealing with MICP appears to be viable, however, to date, all experiments have been carried out in single fractures that are horizontal and planar. MICP treatment in fracture networks with fractures of different aperture and orientation is likely to be more complex. Minto et al. (2016) hypothesized that hydrodynamic feedback between bacteria transport and CaCO₃ precipitation may lead to the sealing of large fractures first resulting in a progressive homogenization of fracture aperture within the network, however this remains to be tested.

297 Much of the work on rock fracture sealing with MICP has been motivated by 298 the context of deep geological disposal of spent nuclear fueld and higher activity

radioactive waste, where MICP could be an alternative grout capable of penetrating into fine aperture fractures with a sufficiently low pH (compared to cement grouts) to not negatively impact on the bentonite buffer performance.

302

303 *Well sealing*

MICP has been proposed for sealing leakage pathways around wells, particularly those that may be used for geological carbon sequestration (Cunningham et al., 2009). Phillips et al. (2013) demonstrated sealing of a large fracture in a 74 cm diameter sandstone core and of a fracture in the sandstone surrounding a real well at a depth of 341 m.

Linked to the potential of MICP for well sealing, are questions concerning how high pressure, high temperature, high salinity, groundwater constituents, anoxic conditions, wellbore cements, and the presence of residual oil, scale inhibitors, surfactants, and other fluids injected to enhance drilling and production, might affect bacterial ureolytic activity and precipitate properties. Of particular concern for CO_2 sequestration is longevity of the seal and the potential for acidic CO_2 saturated water to dissolve CaCO₃ and form wormholes (Minto et al., 2017).

The authors are not aware of any experiments that combine high pressure (>1.5MPa) with temperatures greater than 40°C, however such test will be necessary in order to establish the maximum depth at which MICP may be used for well sealing at depth.

320

321 *Other applications*

322 The focus here has been on the use of MICP for geotechnical applications. However it323 should be noted that MICP is also being investigated for a range of other applications

324 including for bioremediation by co-precipitation of heavy metals and radionuclides 325 (e.g. Mitchell & Ferris, 2005; Fujita et al., 2008; Fujita et al., 2010; Achal et al., 2011, 326 2012a, 2012b), for CO₂ sequestration (e.g. Cunningham et al., 2009; Mitchell et al., 327 2010; Phillips et al., 2013) and for the protection and restoration of concrete and stone 328 (e.g. Bang et al., 2001; De Muynck et al., 2010; Van Tittleboom et al., 2010).

329

330

3.1.3 Control parameters and injection strategies

331 Soil and rock fracture grouting with MICP is fundamentally different to 332 traditional grouting using cements and resins. Numerous methodologies have arisen, 333 among the different research groups studying this process, for the delivery of bacteria, 334 urea, and CaCl₂ so as to best control and optimize CaCO₃ precipitation for different 335 target applications. Table 1. lists the different control parameters and the injection 336 strategies that may influence MICP precipitation. The influence of these and the 337 typical values/ranges that have been used in MICP treatments are discussed in detail 338 in the following.

339 Reagents

340 Bacteria: For engineering applications, the bacterial concentrations used during bioaugmentation mostly fall within the range 0.1 OD_{600} to 1 OD_{600} , corresponding to 341 3.7×10^6 to 8.6×10^7 cells/mL following the relationship developed by Ramachandran et 342 al. (2001) for S. pasteurii, although concentrations greater than 3 OD₆₀₀ have also 343 344 been used (Cheng et al., 2017).

345

346 Fixative: High ionic strength solutions have been used to "fix" bacteria onto media 347 surfaces during bio-augmentation by reducing repulsive surface charges. Harkes et al. (2010) demonstrated that a 50 mM CaCl₂ solution injected after bacterial injection 348

would overtake the bacteria causing the bacteria to flocculate within the porous media and fix them to the media surface resulting in greater bacteria retention and greater precipitation within the desired area. Cuthbert et al. (2013) found that to get sufficient bacterial retention in a fast-flowing fracture, it was necessary to add 200 mM CaCl₂ directly to the bacterial suspension and mix with 400 mM urea resulting in the formation of strongly bound bacteria-CaCO₃ flocs at the point of injection and a 70% retention of injected bacteria within the fracture.

356

Urea and calcium concentrations: Hydrolysing 1 M of urea results in, at most, 1 M CaCO₃, hence, equimolar urea/calcium concentrations are often used for maximum efficiency. However, increasing calcium concentration shifts the saturation state of the system (and can increase pH if adjustment is not made) so excess calcium concentrations (i.e. above the urea concentration) may lead to more rapid precipitation.

Cheng & Shahin (2016) found the maximum amount of CaCO₃ was produced at equimolar urea/CaCl₂ concentrations of 0.4 M with both higher and lower concentrations reducing the total mass of precipitation. Following the same trend, Nemati et al. (2005) found that increasing CaCl₂ alone from 0.045 to 0.27 M resulted in increasing amounts of CaCO₃.

Al Qabany & Soga (2013) found no significant difference between the compressive strength of equimolar 0.1 M and 0.25 M solutions for a given CaCO₃ content. However, as the concentration increased to 0.5 M, slightly more CaCO₃ precipitation was required to achieve the same compressive strength and samples treated with 1 M urea/CaCl₂ frequently failed before testing. This was attributed to larger CaCO₃ crystals forming in the pore space at high concentrations of urea/CaCl₂

and a poor spatial distribution of CaCO₃ resulting in highly heterogeneous samples.
Shahronkhi-Shahraki et al. (2014) on the other hand found unconfined compressive
strength was greater when urea or CaCl₂ concentrations exceeded 0.5 M, although at
these concentrations they did not use equimolar concentrations of urea and CaCl₂.
They observed greater unconfined compressive strength when the urea concentration
exceeded that of CaCl₂ (based on a limited number of specimens).

380

381 pH adjustment: CaCO₃ saturation is dependent on pH hence, by decreasing initial 382 solution pH, a delay in CaCO₃ precipitation can be introduced (Dupraz et al., 2009; 383 Mitchell and Ferris, 2005). Decreasing the cementing solution pH to 6.5 with the 384 addition of hydrochloric acid has been used by Minto et al. (2016), El Mountassir et 385 al. (2014), Tobler et al. (2011) and others, to delay precipitation around the injection 386 point and to allow a greater number of injection cycles before clogging occurs. 387 Gomez et al. (2015) used the same procedure so that bacteria, urea and CaCl₂ could 388 be pre-mixed on the surface and applied without precipitation occurring in the 389 injection tubing.

390

391 Urease activity: The rate of urea hydrolysis is governed by urease activity (measured 392 in mM urea hydrolysed/min), which is determined by the amount of enzyme present 393 in the solution. Given that the bacteria are the source of the enzyme, this is often 394 reported as the specific urease activity K_{urea} , (mM urea/min/OD₆₀₀). K_{urea} is 395 commonly measured using the change in electrical conductivity over a period of five 396 minutes, based on the premise that non-ionic urea is hydrolysed to ionic ammonium. 397 The calibration relationship often used, is that developed by Whiffin (2004), where 398 Urea hydrolysed (mM) = 11.11 x Change in Conductivity (mS/cm). Urease activity values in the range of 0.5 to 60mM urea hydrolysed/min have been reported with
specific urease activity values typically in the range of 0.8 to 29mM urea
hydrolysed/min/OD (Minto et al., 2016; Whiffin, 2004; Harkes et al., 2010; Van
Paassen et al., 2010; Terzis & Laloui, 2018).

Whiffin (2004) investigated the influence of bacterial concentration on 403 404 ureolytic activity for different cultivations of S. pasteurii, and there was observed to 405 be no correlation with biomass; for a given OD_{600} , urease activity varied by more than 406 one order of magnitude. By contrast, Cheng et al. (2017) prepared different bacterial concentrations starting from initial OD₆₀₀ values in the range of 2-2.5 and achieved 407 408 suspensions with low, medium and high urease activities of 5, 10 and 50 µM urea 409 hydrolysed/min, respectively. It should be noted that these levels of urease activity are 410 considerably lower than those reported in other studies using S.Pasteurii (see above). 411 During MICP treatment they kept all other variables constant and found that 412 specimens treated with a lower urease activity suspension resulted in improved 413 treatment, achieving a given unconfined compressive strength at a lower CaCO₃ 414 content (Figure 4). Many researchers have related CaCO₃ content with unconfined 415 compressive strength (UCS), under different experimental conditions (Al Qabany and 416 Soga, 2013; Cheng et al., 2017, 2014, 2013; Choi et al., 2016; Rowshanbakht et al., 417 2016; Terzis and Laloui, 2018; van Paassen et al., 2010), data from these studies are 418 also included in Figure 4 in order to understand the scale of variation. It should also 419 be noted that differences in experimental procedure regarding carrying out UCS tests, 420 can also lead to variability; some researchers use end caps to prepare perfectly flat 421 ends, which can result in higher strengths being achieved than for specimens tested 422 without the use of end caps.

423 The results presented in Figure 4 with respect to urease activity reflect a 424 general trend in the data in the literature in which parameters that act to decrease the 425 rate of ureolysis (low temperature, low urea concentration) or slow CaCO₃ 426 precipitation (low CaCl₂ concentration) results in marginally greater UCS for a given 427 CaCO₃ content. This may be due to the influence of the rate of ureolysis on the 428 amount, size and distribution of crystals. Van Paassen (2009) demonstrated that high 429 rates of ureolysis (>0.3mM urea hydrolysed/min) resulted in the formation of large in 430 (spherical) crystals, whereas intermediate ureolysis rates resulted in smaller calcite 431 crystals and very low rates in a small number of very large calcite crystals.

432 *Flow conditions*

Fluid velocity: Bacterial attachment occurs when cells become physically wedged between grains and trapped in pore throats (straining), or when cells are transported close enough to a surface that electro-static attractive forces overcome repulsive forces. Shear forces imparted by the flow velocity play a role in limiting attachment and can also cause detachment of bacteria (Bakker et al., 2002).

438 In fractures, El Mountassir et al. (2014) and Stoner et al. (2005) have shown that preferential flow paths form when MICP is applied under constantly flowing 439 440 conditions. El Mountassir et al. (2014) showed that hydrodynamic feedback 441 reinforced preferential flow paths at the fluid velocities tested (7.2 to 119 m/hr) and 442 that they remained stable until the injection rate was decreased. This is presumably 443 because at constant flow rates, as permeability decreases due to calcite precipitation, 444 the velocity increases within the remaining open channels, until the shear forces 445 become too high for the bacteria to attach. Minto et al. (2016) proposed that flow 446 velocity could be used to control where bacteria attach (and hence where CaCO₃ 447 precipitates) within a fracture due to the radial flow drop-off in fluid velocity that occurs around a single injection point. It follows that for multiple injection cycles in
radial flow systems, maintaining a constant pressure rather than a constant flow rate,
or sequentially decreasing the flow rate for consecutive cycles, may act to distribute
bacteria over a large area and progressively seal the fracture towards the injection
point.

453 In porous media, the effect of bacterial attachment due to straining and 454 filtration becomes more significant, particularly as the pore throat sizes approach that 455 of the bacterial cells (Tobler et al., 2014)). Tobler et al. (2014) found greater bacteria 456 penetration through a Bentheimer sandstone core as velocities increased (superficial 457 velocity from 0.06 to 0.18 m/hr) and Van Paassen et al. (2009) found little to no 458 CaCO₃ within approximately a 100 mm radius around a spherical injection point in 459 Itterbeck fine sand, corresponding to a superficial flow velocity in the region of 0.4 460 m/hr. This indicates that, even in porous media, velocity can be used to control where 461 CaCO₃ precipitates.

462

463 Static periods: Periods of no flow are often used in lab-scale experiments to allow 464 bacteria to attach to the porous media. Typically, between 0.5 and 1.5 pore volumes of 465 bacteria are injected followed by a static period ranging from 2 to 4 hours (Alvarado 466 and DeJong, 2008; Bernardi et al., 2014; Sham et al., 2013), 12 hours (Shahronkhi-467 Shahraki et al., 2014) or even up to 24 hours (Amin et al., 2017; Cheng et al., 2017). 468 This is followed by the injection of cementing solution which is also often left static 469 for a duration of 24 hours (Amin et al., 2017; Cheng et al., 2017, 2014; Cunningham 470 et al., 2011; Shahronkhi-Shahraki et al., 2014; Sham et al., 2013). Using this 471 approach, each point in the porous media becomes like a batch reactor in which bacteria, urea and CaCl₂ are present with only limited transport due to diffusion. The 472

473 24-hour duration of the static cementation period appears to be motivated by
474 experimental convenience rather than consideration for the amount of bacteria, urease
475 activity, and urea concentration.

476 Ideally during cementation, adequate urea, CaCl₂ and time would be provided 477 for sufficient CaCO₃ precipitation that the bacteria become encased, at which point 478 the reaction ceases. However, due to the Michaelis-Menten kinetics of urea hydrolysis 479 (e.g. Shashank et al., 2018), reaction rates decrease and urea starts to become a 480 limiting factor before it is fully exhausted, hence an unfeasibly long time is required 481 to fully encase the bacteria. To overcome this, some researchers (Bernardi et al., 482 2014; Harkes et al., 2010) inject subsequent volumes of fresh cementing solution, 483 which may not be fully utilised, but may prove more cost effective as the bacteria is 484 are more expensive to grow, process and transport to site than the cementing solution.

485

Single vs cyclic injection: A single injection of ureolytically active bacteria followed
by cementing solution has been shown to be effective for increasing strength in sands
e.g. Whiffin et al. (2007) and Van Paassen et al. (2010) whilst maintaining porosity.
Additional injections of bacteria further increase strength and may result in a more
uniform treatment volume (Cheng and Cord-Ruwisch, 2014; Minto et al., 2017a).
However, they also decrease porosity and thus permeability, which may or may not be
desirable depending upon the application.

When grouting rock fractures, it is necessary to inject multiple cycles of bacteria followed by cementing solution. Each cycle progressively precipitates CaCO₃ on the exposed fracture surface in multiple layers, which are necessary to completely bridge the fracture aperture so as to substantially reduce fracture transmissivity (Cuthbert et al., 2013; El Mountassir et al., 2014; Minto et al., 2016; Tobler et al., in

498 review). When multiple injection cycles are used, it is possible to deliver the same 499 total amount of bacteria, whilst still keeping concentrations close to their optimum 500 values by using an increased number of injections at a lower concentration. An added 501 advantage of this may be more uniform precipitation as preferential flow paths block 502 first, re-directing reagents in subsequent injections (Cheng and Cord-Ruwisch, 2014; 503 Minto et al., in review; van Paassen, 2009).

An alternative approach is a single bacterial injection followed by cementing solution that either contains nutrients or is interspersed with injections of nutrients (Bernardi et al., 2014; Cunningham et al., 2014; Phillips et al., 2013). The aim of the nutrient addition is to stimulate bacteria growth whilst simultaneously precipitating CaCO₃. For this approach to be effective, the relative rate of growth must be an appreciable fraction of the rate of cell death and cell encapsulation within the precipitating CaCO₃; hence it favours slower precipitation rates.

511

512 Medium

513 Mineralogy: MICP has been successfully applied in silica sands, gravel (van Paassen 514 et al., 2012) and organic soil such as peat (Canakci et al., 2015); in porous rock such 515 as Berea sandstone (Cunningham et al., 2014; Minto et al., 2017a; Nemati and 516 Voordouw, 2003); and for fractured rock including dolerite (MacLachlan, 2017), 517 dacite (Cuthbert et al., 2013), granite (Minto et al., 2016), fractured sandstone 518 (Phillips et al., 2016, 2013) and fractured limestone (Ross et al., 2001).

519 Mineralogy has been shown to influence CaCO₃. Studies have reported 520 increased rates of ureolysis and precipitation after initial calcite deposition, suggesting 521 that *S. pasteurii* preferentially attach to these surfaces over silica, glass or 522 polycarbonate (Tobler et al., 2012; Schultz et al., 2011; El Mountassir et al., 2014).

523 Furthermore, the activation energy required for nucleation is typically greater than for 524 crystal growth (e.g. Rodriguez-Blanco et al., 2011) such that CaCO₃ precipitation 525 proceeds more rapidly once calcium carbonate is already present within the system, 526 i.e. arising from an initial MICP treatment or in limestone or marble media.

527

528 Degree of saturation: Lab scale MICP tests are typically performed under fully water-529 saturated conditions, particularly when permeability change is of interest. However, 530 tests that incorporate a drainage step after bacteria injection and cementation (Amin et 531 al., 2017), or were carried out under unsaturated conditions (Cheng et al., 2013), or 532 took place in the field where saturation state could not be controlled (Cheng and 533 Cord-Ruwisch, 2014; Gomez et al., 2015) often report more uniform CaCO₃ 534 distribution and greater depth of treatment.

535 Of all the variables explicitly studied, saturation state has the greatest effect on 536 the CaCO₃/UCS relationship, with lower degrees of saturation during treatment 537 resulting in greater strength for the same amount of CaCO₃ (Figure 5). Cheng et al. 538 (2013) reason that lower saturation concentrates bacteria and reagents at the 539 interparticle contact points. This is likely to be because unsaturated conditions result 540 in a film of liquid occurring at soil particle contact points hence precipitation is 541 concentrated at these contact points where it contributes to strength increase. 542 Furthermore, unsaturated conditions will result in the presence of menisci; bacteria 543 have been observed to preferentially attach at air-water interfaces rather than solid-544 water interfaces (Schäfer et al., 1998), therefore menisci will promote bacterial 545 attachment.

546

When applying MICP reagents, whether by percolation under gravity or a pressurised injection, for a given flow rate the interstitial (or seepage) velocity will increase as saturation decreases. In a similar manner to increasing the fluid velocity, this ought to have the effect of delivering bacteria and urea further into the media before attachment and hydrolysis occur. This may explain the more uniform CaCO₃ distribution and greater depth of treatment observed in samples treated in unsaturated conditions or with unsaturated stages.

554

Soil structure: Van Paassen et al (2009b) demonstrated that initial dry density influences the relationship between CaCO₃ and UCS. In order to achieve the same strength (UCS), a specimen with a lower initial dry density required a greater content of CaCO₃ to be precipitated compared to the same material compacted to a higher initial dry density. While for specimens with the same CaCO₃ content , that compacted to a higher initial dry density exhibited a higher UCS value (Van Paassen et al., (2009b).

562 All studies presented in Figure 6 were conducted in sands of differing particle 563 size and grading and all were treated at the core scale (35-100 mm diameter) with the 564 exception of van Paassen et al. (2010) who cut samples out of a large block of treated sand in a 100 m³ experiment. Terzis & Laloui, (2018) tested a medium and fine sand, 565 566 and showed that the medium sand achieved considerably higher UCS values (and 567 stiffness) for a given $CaCO_3$ content than the fine sand. This is despite the medium 568 sand being initially more porous (Terzis & Laloui, 2018). They determined via micro-569 CT scanning that in the medium sand the diameter of the CaCO₃ bonds (where CaCO₃ 570 bridges particles) created were larger than in the fine sand, reducing inter-particle 571 stresses at contact points, and thus enhancing resistance to shearing. The difference in behavior for the two specimens may also arise from differences in the sand properties,
including for example angularity of the grains, roughness and initial pore structure, all
of which could influence bacterial attachment and precipitation.

875 Recent studies at Arizona State University on Enzymatic Induced Calcium 876 carbonate precipitation have shown an optimum strength for Ottawa 20/30 sand (with 877 a d50 of 400 μ m) reaching 1 MPa at just 1% of CaCO₃, which would fall to the left 878 even of the trendline plotted for Terzis & Laloui (2018) data presented in Figure 6. 879 These studies indicate that initial porosity, the distribution of contact points and area 880 of contact points, in conjunction with the size and distribution of calcite crystals 881 precipitated influences the strength achievable via MICP treatment.

582

583 Environmental conditions

Influence of oxygen concentration: *S. pasteurii* is an obligate aerobe yet conflicting results have been found as to the influence of oxygen on the rate of ureolysis. Mortensen et al. (2011) report higher rates of conductivity change (a proxy measure for ureolysis) for anoxic conditions, as compared with oxic conditions. Tobler et al. (2011) found no significant difference in ammonium production (measured by Nessler assay) when aerobically cultured *S. pasteurii* were injected into oxic and anoxic groundwater.

Parks (2009) found lower growth rates for *S. pasteurii* grown under anaerobic conditions but comparable rates of pH change were observed suggesting comparable rates of ureolysis for aerobic and anaerobic media. When exposed to oxygen, bacterial population growth in the anaerobic media increased, indicating viable cells had survived, but the author notes that growth without oxygen could not be conclusively shown. Whereas Martin et al. (2012) found that S. pasteurii would not actively grow under anaerobic conditions, but that there was still urease activity. These studies indicate that bio-stimulation (i.e. growth of indigenous ureolytic bacteria) may beproblematic in subsurface conditions with limited oxygen supply.

600

601 Pressure: S. pasteurii has been shown to continue to grow and hydrolyse urea at 602 pressures from 7.5 to 10 MPa and at temperatures between 30 and 40°C (Mitchell et 603 al., 2013; Verba et al., 2016). Cunningham et al. (2014) reduced the permeability of a 604 25.4 mm diameter Berea sandstone core at 7.6 MPa whilst Phillips et al. (2016) 605 decreased injectivity into a fractured sandstone around a 341 m deep well where 606 pressure reached 8.3 MPa and downhole fluid temperature was 24.5°C. Mitchell et al. 607 (2013) slowly increased pressure to 7.6 MPa over 20 days so as to allow the bacteria 608 to acclimatize whilst the other researchers do not appear to have taken this precaution.

609

610 Temperature: Increasing temperature acts to increase the rate of ureolysis, for 611 example Van Paassen (2009) found that between 5°C and 70°C the rate of ureolysis 612 doubled approximately every 8°C. However as the ureolysis is driven by the urease 613 enzyme, increasing temperatures leads to denaturation of the enzyme. Illeová et al., 614 (2003) demonstrated using Jack bean urease that all enzyme activity was lost after 615 40mins exposure to a temperature of 87.5°. Zhong and Islam (1995) found S. 616 pasteurii cultivated at room temperature required five days to adapt to a temperature 617 of 50°C but ultimately more CaCO₃ was precipitated at 50°C. Cheng et al. (2017) also 618 found increased CaCO₃ precipitation at higher temperatures, but noted that strength 619 increase was less efficient. Conversely, Wu et al., (2017), investigated urea hydrolysis 620 in the absence of a calcium source, and found decreasing rates of ammonium 621 production at temperatures above 30°C with no ammonium production at 50°C.

622

623 Combination of environmental factors: Environmental factors, including e.g. 624 temperature, pressure, salinity, which may influence MICP are numerous and are 625 interlinked. Furthermore they are also impacted by the injection strategy used. As 626 such at this point it remains unclear from the limited studies presented in the literature 627 on environmental factors as to the individual influence of these parameters on the 628 resulting behavior of MICP treated soil/rock.

629 Indeed, when reviewing data from the literature, it was often clear that there 630 were many combined variables influencing the differences in mechanical behavior 631 observed. Figure 7 presents the UCS vs CaCO₃ for all studies (in grey) and the 632 outliers of all the datasets are highlighted (Van Paassen et al., 2010 and Terzis & 633 Laloui, 2018). Terzis & Laloui (2018) were able to achieve a given unconfined 634 compressive strength at lower calcite contents indicating a more efficient process. 635 Some of the main differences listed between these two studies are highlighted: (i) the 636 urease activity used by Terzis & Laloui (2018) was an order of magnitude lower at 637 1.7mM/min compared to the 18.3mM/min used by Van Paassen et al. (2010), (ii) 638 Terzis & Laloui injected multiple cycles building up layers of calcite precipitation 639 (Terzis et al., 2016), whereas Van Paassen used a single injection sequence (bacteria, 640 followed by fixative, followed by cementing solution), (iii) Van Paassen used whole 641 cells, whereas Terzis & Laloui used lyophilized cells, which may also influence 642 enzyme kinetics (Lauchnor et al., 2015; Graddy et al., 2018; Fidaleo and Lavecchia, 643 2003; Stocks-Fischer et al., 1999). This illustration demonstrates that many different 644 variables play a role in selecting suitable strategies for the deployment of MICP in 645 geotechnical engineering applications.

650 **3.1.4 Challenges and limitations**

651 Uniformity

Uniformity of treatment remains a challenge for MICP. Due to the transport and retention of bacteria and consumption of reagents, it is possible to end up with a greater concentration of cells close to the injection point and a gradient in CaCO₃ precipitation from inlet to outlet. Due to the low viscosity of the MICP solutions, injected material first follows existing preferential flow paths which can lead to inhomogeneous treatment and potentially, pockets of untreated media.

658 However, MICP has been demonstrated to be effective in columns of 5 m length (Whiffin et al., 2007) and in 100 m³ radial injection experiments (van Paassen 659 660 et al., 2010). Methods to improve treatment uniformity are 1) radial injection (which 661 is common in field trials, as opposed to linear injection most often used in lab scale 662 experiments) which increases velocity in the vicinity of the well thus decreasing 663 bacterial attachment, 2) lower the pH of the urea/CaCl₂ cementing solution (typically 664 to 6.5) to introduce a delay between urea hydrolysis and $CaCO_3$ precipitation, and 3) 665 multiple injection cycles of bacteria followed by cementing solution, possibly with 666 lower reagent concentrations, as each cycle will distribute additional bacteria the 667 soil/rock and, hence, treat a different region of the porous/fractured media as flow 668 paths evolve in response to clogging of the pore space with CaCO₃.

669

670 Monitoring

For ground improvement by MICP, monitoring of where, and to what extent, treatment has occurred will be critical. This is also true for ground improvement with traditional cement grouts, however, an empirical body of knowledge has accumulated

674 for cement grouts through their use over hundreds of years which will not initially be675 available for MICP.

At the lab scale, measurement of properties such as changes in mass, 676 677 permeability, shear-wave velocity and X-ray attenuation are effective at establishing treatment effectiveness (DeJong et al., 2006; Minto et al., 2017). At field scale, 678 679 traditional geophysical monitoring techniques such as ground penetrating radar, 680 electrical resistivity tomography, soil self-potential, ultrasound and seismic surveys 681 may prove effective, together with monitoring injection pressures, cross-hole 682 conductance testing (Cuthbert et al., 2013) and NMR well monitoring (Kirkland et al., 683 2017).

684

685 *Modelling and predicting*

Several models have been produced to fit lab-scale and field experimental
data. These mostly use simplified geochemistry in 1D (Ebigbo et al., 2012; Fauriel
and Laloui, 2012; Hommel et al., 2016; Martinez et al., 2014) or 2D (Cuthbert et al.,
2013; van Wijngaarden et al., 2016). Those that use more complete geochemical
models such as PHREEQC are limited to 1D (Barkouki et al., 2011; Dupraz et al.,
2009; Wu et al., 2011) or 2D with between four (Qin et al., 2016) and 17 (Zhang and
Klapper, 2010) reactive species.

Published 3D models are limited to Nassar et al. (2018) which, together with van Wijngaarden et al. (2016) and the authors' own as yet unpublished model (Figure 8) may be the only models with sufficiently complex reactive transport and flexible boundary conditions together with simplified and tractable geochemistry to be of use at field scale.

698 Given the complex nature of the MICP process, reliable predictive models for 699 field-scale do not currently exist. These engineering models allow us to explore the 700 consequences of a range of possible injection strategies in silico, with the aim of 701 narrowing them down to those worth testing experimentally.

702

703 *By-products*

704 The main by-product of MICP is ammonia/ammonium (often in the odourless 705 form ammonium chloride) which is considered a groundwater pollutant that is toxic to 706 aquatic organisms and can cause algal blooms at high concentrations. In order to gain 707 regulatory approval, Cuthbert et al. (2013) had to extract from a separate borehole at 708 five times the rate of injection so as to collect the majority of ammonium produced in 709 their field trial. Esnault-Filet et al. (2012) collected ammonium chloride and paid for 710 treatment of it at a local wastewater treatment works. Other field tests do not report any regulatory requirement to collect, treat, or limit the production of ammonium 711 712 (Gomez et al., 2015; Phillips et al., 2016) and this is likely to reflect whether or not 713 MICP is being carried out in a sensitive environment or close to drinking water 714 supplies.

715

716 Upscaling

For MICP to make the jump from field trials to a practical engineering ground improvement method, it will be necessary to massively upscale the process. Preparation of the cementing solution should pose no issue as $CaCl_2$ is available in large quantities either as food grade or industrial grade (e.g. road de-icing salt) and urea is mass produced as fertiliser. Both could be transported dry and mixed to the desired concentration on site.

723 Growth of bacteria may be more challenging to upscale, however two 724 promising methods have been tested in the field: stimulation of naturally occurring 725 ureolytically active bacteria in the ground (biostimulation) which requires no special 726 bacteria culturing equipment nor transport and handling of bacteria (Gomez et al., 727 2018); or the approach demonstrated by (Van der Star et al., 2009) who started from a 728 moderately large volume (100 L) of pure-strain S. pasteurii grown under sterile 729 conditions in the lab which was used as a seed culture to inoculate a 5 m^3 on-site bio-730 reactor (bioaugmentation). In this case, less than sterile growth conditions were 731 acceptable because ureolytically active bacteria tend to out-compete other strains 732 when ammonia is present or urea is available (Graddy et al., 2018) and the initial 733 concentration of S. pasteurii added to the bio-reactor would likely be orders of 734 magnitude greater than that of any competing strains.

735

736

737 **3.2** Microbially induced carbonate precipitation via denitrification

738 **3.2.1 Process**

Whilst MICP by urea hydrolysis is the process most widely studied, for a range of engineering applications (Phillips et al. 2013), there are various other processes which may result in precipitation of calcium carbonate, among which denitrification based MICP is considered the most promising (Van Paassen et al, 2010b). As part of the nitrogen cycle, denitrification (also known as dissimilatory reduction of nitrate) is a process naturally occurring in the subsurface, in which organic matter is oxidized to inorganic carbon and nitrate is reduced to nitrogen gas.

The reduction of nitrate (NO_3) to nitrogen gas (N_2) goes through several intermediate reactions, which involves specific enzymes and the formation of

748 intermediate nitrogen compounds: nitrite (NO₂⁻), nitrous oxide (N₂O), and nitric oxide (NO) (Rebata-Landa and Santamarina, 2012). Accumulation of these intermediates 749 750 should be avoided as nitrite and nitric oxide are toxic and inhibit microbial growth and nitrous oxide is a very strong greenhouse gas (Almeida, Julio et al. 1995; Chung 751 and Chung 2000; Zumft, 1997; Madigan et al. 2012, Pham et al, 2016). In order to 752 753 enable the efficient and full reduction of nitrate to nitrogen gas, selecting the right 754 substrate composition is essential (O'Donnell 2016, Pham et al. 2016). Too much 755 nitrate may lead to accumulation of intermediate compounds, whilst leaving a large 756 excess of organic substrate would be inefficient.

Although various organic substrates can be used to stimulate denitrification in the subsurface, most studies have used a solution containing calcium acetate and calcium nitrate (Van Paassen 2009; Van Paassen et al. 2010; Van der Star et al., 2012; Kavazanjian et al., 2015, Hamdan et al. 2017; Pham et al. 2016), for which the catabolic reaction is written as:

762

763
$$C_2O_3H_2^- + 1.6NO_3^- + 0.4H_2O \rightarrow 0.8N_2 + 2HCO_3^- + 0.6OH^-$$
 (4)

764

This catabolic reaction provides the energy for indigenous denitrifying microorganisms to grow. At maximum growth, a significant amount of substrates will be converted to biomass. The resulting metabolic reaction at maximum growth can be written as (van Paassen et al., 2017, Pham 2017):

769

770
$$1.21C_2H_3O_2^- + 0.97NO_3^- + 0.17H_2O \rightarrow CH_{1.8}O_{0.5}N_{0.2} + 0.39N_2 +$$
(5)

771 1.41HCO₃⁻ + 0.76OH⁻

The actual growth rate is often limited due to limited availability of substrates, nutrients or trace elements, or due to accumulation of intermediate compounds. As a result the actual metabolic reaction stoichiometry varies between conditions of maximum growth (5) and zero growth, which corresponds to the catabolic reaction (4).

By using soluble calcium salts as substrates, the produced inorganic carbon
precipitates as calcium carbonate:

(6)

780

781 $Ca^{2+} + HCO_3^- \rightarrow CaCO_3 + H^+$

782

Calcium carbonate (CaCO₃) precipitation buffers the pH as it consumes the alkalinity produced by reduction of the nitrate. Maintaining a stable pH helps to prevent the accumulation of toxic intermediate nitrogen compounds and stimulates microbial growth (Pham et al., 2016). O'Donnell (2016) showed that a mixed microbial community developed by bio-stimulation in a natural soil was more efficient at denitrification than a pure culture of a well-known denitrifying bacteria, pseudomonas denitrificans.

790

791

792 **3.2.2 Hydro-mechanical behavior and applications**

Similar to biomineralization by urea hydrolysis, CaCO₃ precipitation by denitrification can reduce soil permeability by filling up the pore space or increase soil strength, stiffness and dilatancy by coating and roughening the soil particles or creating cementitious bonds at the particle contacts (Figure 9). O'Donnell et al. (2017) reported that CaCO₃ precipitation of 1 to 2% (by mass) was sufficient to increase

798 cyclic shear strength in cyclic direct simple shear tests by 40% on both natural and 799 laboratory standard sands. Pham et al. (2018) found that treatment resulting in a 800 CaCO₃ content of 0.65% more-than-doubled the small strain stiffness under static 801 compressive loading conditions. Through shear wave velocity measurements 802 O'Donnell (2016) observed that sands treated by denitrification showed a greater 803 improvement in the shear stiffness of the soil when compared to ureolysis-treated 804 specimens at the same carbonate content. This was attributed to bigger calcite crystals 805 due to the slow rate of precipitation via denitrification. Precipitation was also more 806 dominant at inter-particle contacts due to interaction between gas bubbles and 807 precipitation. O'Donnell (2016) also showed that after failure, when samples treated 808 by MICP via denitrification were de-aggregated and reconstituted they retained some 809 increase in static and cyclic strength and stiffness (compared to untreated soils), 810 which was attributed to particle surface roughening.

811

812 3.2.3 Challenges and limitations

813 While recent results for urea hydrolysis have shown that ureolytic bacteria can be 814 stimulated in situ, in most cases MICP through urea hydrolysis still requires ex situ 815 cultivation and injection of (specific) ureolytic bacteria. The main advantage of MICP 816 by denitrification is that the process does not require ex situ cultivation. The substrate 817 solution will stimulate indigenous denitrifying bacteria. Secondly, if nitrate is 818 completely reduced to nitrogen gas the process does not leave any toxic by-products. 819 The absence of a harmful by-product (e.g., ammonium chloride) is another potential 820 advantage of denitrification over ureolysis. However, compared to urea hydrolysis, 821 MICP via denitrification is a relatively slow process (Martin et al. 2013; Van Paassen 822 et al. 2010) Van Paassen et al. (2010b). For continuously cycled substrate solutions,

823 over a period of 100 days, Van Paassen et al. (2010b) reported precipitation ranging 824 from 1 to 9.5% CaCO₃ (by mass). O'Donnell et al (2017) required 30 flushes over a 825 period of 400 days to precipitate approx. 2.5% CaCO_{3.} Pham et al. (2018) aimed to 826 optimize treatment protocol and showed that using a large number of flushes with low 827 concentrated substrate solution resulted in a more efficient conversion than a low 828 number of flushes with high concentrated substrate solution, they obtained 0.65% 829 CaCO₃ in 15 flushes in 35 days. The low rate at high concentrations may be the result 830 of inhibition by toxic intermediates or limited substrate availability. This implies that 831 a lower initial nitrate concentration provides a more efficient environment for MICP 832 via denitrification (Hamdan et al. 2017). The consequence of the low reaction rate and 833 the preferred use of low concentrations is that a larger volume of solution needs to be 834 injected and a long treatment time is required. Another result of the low reaction rate 835 is that the precipitation process generates a relatively low number of large crystals. 836 The effect of crystal size and distribution on the mechanical performance still requires 837 further investigation. Another challenge to be solved is the interaction between the 838 different product, CaCO₃ minerals, nitrogen gas and biomass. Although by-products 839 of the denitrification reaction are not toxic, they do affect the hydro-mechanical 840 behavior of soils and may affect the crystallization process. For example, during the 841 experiments reported by Pham et al. (2018), hydraulic conductivity reduced 842 significantly, which was mainly attributed to the combined formation and entrapment 843 of nitrogen gas and biomass.

844

845

846

848 **3.3 Biogenic gas formation via denitrification**

849 **3.3.1 Process**

Although biogenic nitrogen gas may be considered as a by-product of MICP via 850 851 denitrification, as described in the previous section, several recent studies have 852 investigated the potential use of biogenic nitrogen gas alone for ground improvement 853 (He et al. 2013; He and Chu 2014; Kavazanjian et al. 2015, Pham et al. 2016, 854 O'Donnell, 2017a). The most common biogenic gases that are formed in the 855 subsurface are methane (CH_4), nitrogen (N_2), hydrogen sulphide (H_2S), and carbon 856 dioxide (CO₂). These gases are the product of metabolic processes of microorganisms. 857 As nitrogen gas has a low solubility and is neither toxic nor a greenhouse gas, 858 biogenic production of nitrogen gas is considered to be the most appropriate candidate 859 for ground improvement via biogenic gas generation (Van Paassen et al. 2017). As 860 shown in the previous section, the amount of nitrogen gas produced depends on the 861 metabolic conversion. Depending on the growth rate of the bacteria the yield of 862 nitrogen gas over nitrate (N_2/NO_3) ranges from 0.4 to 0.5. However, the volume of 863 produced gas depends on the solubility, bubble size, pore pressure and partial pressure 864 of the gas phase. Van Paassen et al. (2017) presents a theoretical framework for 865 estimating the volume of gas produced by a biogenic process and the resulting degree 866 of saturation, combining Henry's law and the ideal gas law. The results show that for 867 a given amount of produced substrate consumption the resulting gas saturation 868 decreases with depth, due to an increase in pressure and gas solubility.

869

870 **3.3.2 Hydro-mechanical behavior and applications**

871 The presence of entrapped biogenic nitrogen gas in the pore volume may significantly

affect the hydro-mechanical behavior of the soil. The presence of gas can significantly

873 reduce the hydraulic conductivity of soils, even if it fills up a small fraction of the 874 pore space (Ronen et al., 1989; Baird & Waldron, 2003; Mahabadi and Jang, 2014; 875 Mahabadi et al. 2016). Biogenic nitrogen gas production may also mitigate both static 876 liquefaction (He and Chu 2014; Pham et al. 2016) and earthquake-induced 877 liquefaction (Rebata-Landa and Santamarina 2012; He et al. 2013; Kavazanjian et al. 878 2015). The gas phase increases the compressibility of the pore fluid (Biot, 1941; 879 Tsukamoto et al. 2002; Ishihara et al., 2004), which dampens pore pressure build up 880 during monotonic and cyclic undrained loading (Yang et al. 2004; Yegian et al. 2007, 881 He and Chu 2014) It has been shown that small levels of desaturation can increase 882 liquefaction resistance significantly (Ishihara and Tsukamoto, 2004; Okamura and 883 Soga, 2006). For example He et al. (2013) demonstrated that by desaturating a clean 884 coarse sand through denitrification, to a degree of saturation of 80 to 95%, they could 885 significantly dampen pore pressure build up, prevent loss of bearing capacity and 886 significantly reduce settlements arising from surface loading. O'Donnell (2016) 887 reported reaching a degree of saturation of approximately 94% via biogenic gas 888 formation within 1 to 3 days in laboratory columns using a clean, uniform medium 889 fine sand and demonstrated that a 40% increase in cyclic shear strength was obtained 890 upon cyclic simple shear testing of specimens at this degree of saturation.

891

892 **3.3.3 Challenges and limitations**

The potential of using biogenic nitrogen gas to reduce hydraulic conductivity or to increase liquefaction resistance seems promising. Particularly because the amount of substrates required to generate a significant amount of desaturation is very low. A single flush containing 50 mM dissolved nitrate is sufficient to fill up 48 to 60% of the pore volume with nitrogen gas close to the surface or 14 to 16% of the pore

898 volume at 25 m below the groundwater level. Another advantage of microbially 899 induced desaturation through denitrification is that desaturation can be achieved over 900 large areas through bio-stimulation of indigenous soil bacteria, which can reduce 901 some of the challenges encountered when using bioaugmentation, enhancing gas 902 distribution compared to abiotic gas injections. However, in order to rely on the gas 903 phase to improve liquefaction resistance, long-term persistence of the gas phase must 904 be ensured. Although Okamura et al. (2006) and Eseller-Bayat et al. (2013) reported 905 that abiotically induced desaturation can persist for periods of several years, the gas 906 may escape through upward migration and/or dissolution or through convective and 907 diffusive transport through groundwater. The amount of gas which can be trapped in 908 the pore space depends on the pore size distribution and connectivity between the 909 pores. When gas bubbles are smaller than the pore throats between the grains, they 910 may easily migrate upwards due to buoyancy. Once the bubbles increase in size they 911 may get trapped at pore throats. If additional gas is being produced the bubble can 912 only migrate further if pressure in the bubble exceeds the capillary pressure or air 913 entry pressure required to squeeze through the pore throat. In this way the gas phase 914 gradually forms a network of gas filled pores, until it finds a zone of higher 915 permeability, which allows the gas network to vent and rapidly migrate upward. If 916 upward migration is restricted by a low permeability layer (e.g. clay), gas pockets 917 may form, and if the gas pressure exceeds the overburden pressure then cracks may 918 form in the soil as the soil above the gas pocket may be lifted up (Sobkowicz and 919 Morgenstern, 1984; Grozic et al., 1999; Leroueil et al. 2015). An excess amount or 920 sudden rapid venting of trapped gas may reduce bearing capacity and is considered a 921 major hazard for offshore foundations. Considering the durability of the gas phase and 922 that its potential to mitigate liquefaction may be limited, a number of authors suggest 923 the use of biogenic gas formation as the first step in a combined two-stage process of 924 desaturation and carbonate precipitation via denitrification (O'Donnell, 2017a,b). In 925 particular, this has been considered for mitigating liquefaction, where gas formation 926 provides enhanced resistance in the short term and calcium carbonate precipitation 927 provides enhanced resistance in the long term (Kavazanjian et al. 2015; Khodadadi et 928 al. 2017; O'Donnell 2016).

929

930

931 3.4 Fungal hyphal networks

3.4.1 Introduction

The benefits of harnessing bacterial processes in soils are now being widely investigated within the geotechnical engineering community. Fungi, however, despite accounting for up to 25% of the biomass on earth (Miller, 1992) are rarely considered, and only in a problematic context (e.g. human exposure to molds, Geostrata, 2003). However, of the 99,000 known fungal species, less than 0.3% are pathogenic to humans and animals and less than 10% are capable of colonising plants; an even smaller fraction of these are plant pathogens (Carris et al., 2012).

940 The classification of fungi into phyla, historically considered to include 941 Ascomycota, Basidiomycota, Chytridiomycota and Zygomycota (e.g. Webster and 942 Weber, 2007) is continuing to change as research provides more evidence for further 943 differentiation and exapansion of the kingdom (introduction of Glomeromycota and Microsporidia phyla). Regardless of their classification, soil fungi can generally be 944 945 considered as falling into the following main categories: (i) saprotrophic (i.e. 946 decomposers) that digest dead organic matter (dead wood, leaf litter producing fungal biomass, carbon dioxide and other compounds such as organic acids, which are of 947

948 critical importance for nutrient cycling in soils, (ii) pathogenic or parasitic fungi that 949 colonise hosts (e.g. plants or other organisms) causing disease and (iii) fungi that exist 950 in symbiotic relationships these include mycorrhizal fungi (ectomycorrhizal and 951 arbuscular mycorrhizal) which live in a mutually beneficial symbiotic relationship 952 with plants increasing their uptake of nutrients and water (e.g. nitrogen and 953 phosphorus) and protecting against soil pathogens, and lichens which live in 954 symbiotic relationships with algae and cyanobacteria (Jeffries et al., 2003; Konhauser, 955 2007; Hoorman, 2011).

956 Fungi have widely ranging morphologies from single-celled yeasts to multi-957 cellular fungi, that is, fungi that predominantly grow through the development of 958 hyphae. Hyphae are multi-cellular tube-like structures, consisting mainly of chitin (a polysaccharide containing nitrogen), typically with diameters in the range of 1 - 30959 960 µm and lengths from several microns to several metres (Islam et al., 2017). Hyphae 961 can branch into multiple hyphae, and, anastomose creating complex three-962 dimensional networks. The mass of branching hyphae is known as the mycelium. A 963 densely packed mass of hyphae can form into sclerotia, consisting of a hardened 964 aggregated mass of hyphae containing food reserves. Sclerotia may form when 965 nutrients are scarce, although other stimuli can also trigger their formation (Money, 966 2016).

967

968 3.4.2 Fungi-soil interactions

Fungi are known to play an important role in soil aggregation, both in the formation of aggregates and in maintaining aggregate stability (Lynch and Bragg, 1985, Rillig, and Mummey, 2006). From an agricultural perspective soil aggregate stability is important for maintaining transport of air, water and nutrients within the

soil. From a geotechnical engineering perspective the aggregation of soils influences
their hydraulic behavior (i.e. permeability and water retention capability) (e.g. Juang
& Holtz, 1986, Barbour, 1998, Vanapalli et al., 1999) and their mechanical behavior
(Barden & Sides, 1970; Alonso et al., 1987). Although it is widely acknowledged that
aggregated soils are encountered within geotechnical engineering (e.g. Collins &
McGown, 1974, Alonso et al., 1987) little, if any, consideration has been given to the
role of microorganisms in the formation or stability of aggregates in this context.

980 Studies by soil and agricultural scientists have observed increased size of 981 aggregates formed in soils inoculated with fungi and enhanced resistance to 982 breakdown upon wetting, for a range of different fungal species including mycorrhizal 983 and saprotrophic species (e.g. Tisdall and Oades, 1979; Tisdall and Oades, 1982; 984 Degens et al., 1996; Caesar-TonThat and Cochran, 2000, Caesar-ThonThat, 2002, 985 Peng et al., 2013). Rillig & Mummey (2006) outline three categories of mechanisms 986 by which fungi (focused on arbuscular mycorrhizal fungi, AMF) can contribute to soil 987 aggregate stability: (i) Biophysical, (ii) Biochemical and (iii) Biological mechanisms.

988 The biophysical influence of fungal hyphae is similar to the action of plant 989 roots (although at a smaller scale) where hyphae act to enmesh and entangle soil 990 particles, binding micro-aggregates together (Tisdall & Oades, 1982). The effects of 991 plant roots are well-studied, they bind soil particles and aggregates together providing 992 an additional apparent cohesion against shearing (Stokes et al., 2009). The level of 993 reinforcement provided is dependent on root tensile strength and root architecture 994 (e.g. root diameter, root length density). Greater shearing resistance is provided by 995 many smaller diameter roots than by a smaller number of larger diameter roots, where 996 the fraction of the soil plane occupied by the plant roots is the same. (Stokes et al., 2009). By drawing similarities with plant root reinforcement literature, the mechanism 997

998 by which fungal hyphae bind particles and aggregates might also be expected to 999 depend on the morphological properties of the fungal networks (e.g. hyphae diameter, 1000 density, and interconnectivity) and the tensile strength of the different strains of 1001 fungal hyphae (Rillig & Mummey, 2006). However, little is known of how these 1002 properties vary between different species and strains. Hyphae may also be 1003 hypothesised to contribute to water transport and retention in soils, ultimately 1004 inducing wetting and drying cycles on a localised-scale (Rillig & Mummey, 2006) 1005 which may influence binding of soil particles to hyphae and influence mechanical 1006 behavior of micro-aggregates; these effects remain largely unexplored. Additionally, 1007 the growth of fungal hyphae have been observed to influence soil structure by 1008 aligning clay particles along hyphae, due to the stress exerted on soil particles during 1009 growth, possibly even forming micro-aggregates (Rillig & Mummey, 2006).

1010 In terms of synthetic fibers, it has been widely reported in geotechnical 1011 engineering that the addition of fibers increases soil strength (i.e. compressive, shear 1012 or tensile strength at failure) and increases strain to failure (i.e. increased ductile behavior) (e.g. Ranjan et al., 1996; Santoni et al., 2001, Michalowski & Čermák, 1013 1014 2003). The reinforcing effect increases with increasing fiber content (up to a limit) 1015 and increasing aspect ratio (length/diameter) (e.g. Michalowski & Čermák, 2003). 1016 Fungal hyphae can be considered to be micro-scale roots with a very high aspect ratio. 1017 Furthermore, unlike synthetic fibers fungal hyphae may also exhibit anastomosis 1018 forming complex interconnected three-dimensional networks with further potential for 1019 entanglement and enmeshment of soil particles and aggregates.

1020 Soil aggregate formation and stability are also influenced by biochemical 1021 processes. Fungal hyphae are known to secrete biochemical products into their 1022 surroundings (exudates), as well as containing products in their hyphal walls, that may

1023 after decomposition persist in the soil (Rillig and Mummey, 2006). Chenu (1989) 1024 demonstrated that scleroglucan (a fungal polysaccharide) improved the stability of kaolinite and montmorillonite aggregates, and increased clay porosity. Glomalin-1025 1026 related soil protein has been correlated with soil aggregate stability for AMF amended 1027 soils (e.g. Wright and Upadhyaya, 1996, 1998; Rillig 2004) and is thought to act as a 1028 'glue-like' substance. Studies by Caesar-TonThat & Cochran, (2000) and Caesar-1029 ThonThat, (2002) on a saprotrophic species highlighted the importance of insoluble 1030 extracellular compounds polysaccharides on the water stability of aggregates 1031 amended with a saprotrophic fungus. Comparing aggregate stability for soils 1032 inoculated with fungi with those inoculated with liquid media in which the 1033 microorganisms were grown, demonstrated that the binding agents remain in close 1034 association with the hyphae and are not excreted into the liquid/soil media (Aspiras et 1035 al., 1971).

1036 Filamentous or mycelia-forming fungi such as those belonging to the 1037 Ascomycota Basidiomycota phyla are also known to secrete proteins called hydrophobins (Wessels et al., 1991; Wessels, 1996). Hydrophobins play varied roles 1038 1039 in the functional processes that occur throughout the growth and life cycle of fungi 1040 including, modification of environmental conditions to allow sporulation and aerial 1041 hyphae formation (Wessels, 1996; Wösten et al., 1999; van Wetter et al., 2000), 1042 mediation of hyphal attachment to surfaces, substrate colonisation (Wösten et al., 1043 1994; Temple et al., 1997) and involvement in the production of fruiting bodies 1044 (Lugones et al., 1999). Hydrophobins self-assemble at surficial interfaces forming 1045 amphipathic (or amphiphilic) layers capable of altering surface wettability. Given the 1046 role of hydrophobins in aiding fungal hyphae attachment to surfaces, and the role in altering surface properties, it is envisaged that these proteins also play a role in soilaggregation (Rillig & Mummey, 2006).

Finally, in terms of biological mechanisms, fungi may influence the location and density of microbial populations in the soil, for example exudates may act as substrates for bacterial growth, which could also impact on the formation or stability of soil aggregates (Rillig & Mummey, 2006).

1053 The extent of the role played by each mechanism within a given soil will be 1054 highly dependent on the fungal type and species (or indeed community as a whole) 1055 and the soil composition, grain size and pore size distribution. For example, Aspiras et 1056 al., (1971) demonstrated by sonicating fungal inoculated aggregates, that aggregate 1057 stability was not greatly reduced, despite the hyphal network being disrupted, 1058 concluding that the role of binding substances, (mainly polysaccharides) is more 1059 important than the physical entangling effect of the hyphae for clayey soils (where 1060 clay content was >25%). Whereas Degens et al., (1996) demonstrated for sandy soils 1061 that aggregation could be attributed to increases in hyphal length, with hyphae 1062 observed via Scanning Electron Microscopy to cross-link sand grains together via short hyphal lengths. Furthermore Degens et al., (1996) observed no difference 1063 1064 between the hot-water extractable carbohydrate carbon content of aggregated and 1065 non-aggregated soils, indicating that microbial polysaccharides were not in this case 1066 the dominant mechanism controlling aggregation. What is not yet clear is how 1067 aggregations on a local scale, formed or maintained stable via fungal activity, may 1068 influence the bulk hydraulic and mechanical behavior of soil.

- 1070
- 1071

1072 **3.4.3 Hydro-mechanical behavior and applications**

1073 Fungi are ubiquitous in soils and the observations of fungi soil-interactions outlined above support the proposal that fungal growth could indeed be engineered for 1074 1075 geotechnical engineering applications. To date, the use of fungi for soil improvement 1076 applications has been largely limited to the combined study of plant-mycorrhizal 1077 systems (e.g. Mardhiah et al., 2016; Graf & Frei, 2013, Jeffries et al., 2003), in eco-1078 engineering studies. The introduction of mycorrhizal fungi has mainly been 1079 considered as a means to enhance plant growth for successful re-vegetation of 1080 degraded soil systems following erosion, landslide or desertification (e.g. Requena et 1081 al., 2001, Caravaca et al., 2003). The presence of mycorrhizal fungi promotes the 1082 formation and stability of aggregates acting as stores for nutrients and water for plant 1083 growth (Tisdall & Oades, 1982), thus accelerating and aiding plant colonisation (Graf 1084 & Frei, 2013, Jeffries et al., 2003, Peng et al., 2013). Furthermore, mycorrhizal have 1085 been shown to increase root production, root length density and for some species even 1086 enhance plant root tensile strength (Stokes et al., 2009). Peng et al., (2013) 1087 demonstrated that independent of the involvement of plant roots, hyphal networks 1088 have a positive impact on the stability of soil aggregates. The mechanisms by which 1089 arbuscular mycorrhizal fungi may influence soil aggregations are expected to be 1090 similar for other types of fungi (Rillig & Mummey, 2006). Furthermore, considering 1091 that binding substances are known to be closely associated with hyphal surfaces for a 1092 range of fungal types (Aspiras et al., 1971), it is proposed that other fungal species 1093 could by themselves also be considered for soil improvement applications, for 1094 example to enhance resistance against water or wind-induced erosion (Tisdall et al., 1095 2012; Mardhiah et al., 2016;).

1096 Researchers at the University of Strathclyde (El Mountassir and Salifu) have 1097 been investigating the hydro-mechanical behavior of fungal inoculated soils over the past two years. Early results based on engineering the growth of *Pleurotus ostreatus* 1098 1099 demonstrate that fungal hyphae can result in the enmeshment and entanglement of 1100 sand particles (Figure 10A), with hyphae and sclerotia turning loose sand into a 1101 cohesive mass (Figure 10C). Water drop penetration tests conducted on fine sands 6 1102 days after inoculation with *Pleurotus ostreatus*, indicate that the fungal treated sand 1103 exhibits extreme hydrophobicity; 10µL water droplets did not penetrate the sand 1104 where mycelium growth was visible even after 24hrs (Figure 10B), whereas 1105 penetration was immediate (within several seconds) in the non-inocculated control 1106 samples. These results are promising for the deployment of fungi in a range of ground 1107 engineering applications where enhanced cohesion, or the ability to control surface 1108 wettability is desirable.

1109 Finally, for geotechnical applications where greater soil strength may be 1110 desirable, than that which can be achieved by hyphae and its associated products 1111 alone, fungal biomineralisation processes could be triggered. Fungi are known to play 1112 a significant role in mineral formation and transformations in the natural environment 1113 (e.g. Gadd 2007, Gadd, 2017) and can induce biomineralisation by nucleating and 1114 precipitating minerals, most commonly carbonates and oxalates, on or within cell 1115 walls (Gadd, 2007; Gadd, 2017). Some fungi are known to precipitate calcium 1116 carbonate extra-cellularly and urease positive fungal strains can also break down urea 1117 resulting in the formation of calcium carbonate in a calcium rich environment (Li et 1118 al., 2014; Kumari et al., 2016; Li and Gadd., 2017).

1119 Given the vast number of different fungal species and variations in their 1120 behavior there is huge scope for their deployment in geotechnical engineering. It is

1121 envisaged that ground improvement technologies incorporating fungi could be 1122 relatively cheap given that treatment of soil surfaces could be conducted in a 1123 relatively easy manner over potentially large areas.

1124

1125 **3.4.4 Summary**

The use of fungal hyphal networks in ground improvement is a new avenue of research within biogeotechnics, with many open questions. To begin to investigate the feasibility and limitations of their deployment from an engineering perspective, a better understanding of the possible changes to soil behavior that can be induced by fungal inoculation is needed for a range of fungal species.

1131

1132 **4. CONCLUSIONS**

1133 During the last 10-15 years, geotechnical engineers have started to consider 1134 the use of microbial processes in the development of novel nature-inspired ground 1135 improvement technologies. MICP via ureolysis, is the process which has gained the 1136 most attention within the geotechnical community to-date, with many research groups 1137 worldwide investigating the process and injection strategies for its deployment. It is 1138 evident that there are numerous control parameters and variables related to the 1139 reagents, flow conditions, the medium in which it is to be deployed and 1140 environmental conditions, which all influence the hydro-mechanical behavior of the 1141 resulting treated soil or rock volume. These all need to be considered in order to 1142 design suitable strategies for its use in geotechnical engineering applications. Other 1143 microbial processes also being considered for the manipulation of the hydraulic and 1144 mechanical behavior of the ground include MICP via denitrification and biogenic gas 1145 formation. Although, it is clear that there remain a whole host of microbial processes

that could be explored by geotechnical engineers. This review outlined one such areafor investigation: the potential engineered growth of fungi in soils.

Aside from the development of new technologies, there is an additional opportunity for geotechnical engineers to enhance their understanding of existing soil behavior by considering the role that microorganisms play in the formation of soil particles and soil structure. In order to achieve this aim and that of novel ground improvement technologies, increased collaboration between geotechnical engineers and geomicrobiologists will be required in order to explore more fully a wider range of microbial processes under both natural and engineered conditions.

TABLES

Reagents	Bacteria concentration \pm use of fixative
	Urea and calcium concentrations
	pH adjustment
	Urease activity
Injection strategy	Fluid velocity
	Static treatment periods
	Single/Cyclic injection
Medium	Porous/Fractured
	Mineralogy
	Degree of saturation
	Soil structure (Grain size & pore size distribution,
	density)
	Particle shape & roughness
Environmental Conditions	Temperature
	Pressure
	Salinity of pore fluid
	Anoxic/Oxic

1894Table 1. Control parameters and variables in MICP treatments

FIGURE CAPTIONS

- Figure 1. SEM image of CaCO3 precipitate resulting from urea hydrolysis. Indentations within the CaCO3 are a result of S. pasteurii cells in the process of being encapsulated.
- Figure 2. Loose sand before and after treatment with MICP.
- Figure 3. Surficial treatment of sand for erosion reduction. White CaCO₃ concentrated at the top of the sample forms a low permeability erosion resistant layer that extends approximately 10 mm into the silica sand.
- Figure 4. Relationship between CaCO₃ content and unconfined compressive strength for all studies (grey circle outlines: data from Al Qabany and Soga, 2013; Cheng et al., 2014, 2013; Choi et al., 2016; Rowshanbakht et al., 2016; Terzis and Laloui, 2018; van Paassen et al., 2010) with comparable urease activity highlighted (Cheng et al., 2017).
- Figure 5. Relationship between CaCO₃ content and unconfined compressive strength for studies in which saturation was either fully saturated or not recorded (grey circle outlines: (Al Qabany and Soga, 2013; Cheng et al., 2017, 2014; Choi et al., 2016; Rowshanbakht et al., 2016; Terzis and Laloui, 2018; van Paassen et al., 2010) with controlled saturation states highlighted (Cheng et al., 2013).
- Figure 6. Relationship between CaCO₃ content and unconfined compressive strength for all studies (grey circles) (Al Qabany and Soga, 2013; Cheng et al., 2017, 2014; Choi et al., 2016; Rowshanbakht et al., 2016) with datasets highlighted (Terzis and Laloui, 2018) comparing medium and fine sand.
- Figure 7. Relationship between CaCO₃ content and unconfined compressive strength for all studies (grey circles) (Al Qabany and Soga, 2013; Cheng et al., 2017, 2014; Choi et al., 2016; Rowshanbakht et al., 2016) with outlier datasets highlighted (Terzis and Laloui, 2018; Van Paassen et al., 2010).
- Figure 8A. Schematic representation of the coupled 3D model of MICP treatment processes developed at the University of Strathclyde. B. Predicted CaCO₃ precipitation, using the University of Strathclyde model, for MICP treatment using a single injection well within a heterogeneous sand.
- Figure 9. Calcite crystals formed via microbial denitrification bridging silica sand grains.
- Figure 10A. Hyphae of Pleurotus ostreatus enmeshing sand grains imaged under an optical microscope, B. Growth of mycelium of Pluerotus ostreatus in fine sand 6 days after inoculation with P.ostreatus. Water drop penetration tests showed that water droplets of 10µL did not penetrate even after 24hrs. C. Hyphae and sclerotia of Pleurotus ostreatus binding originally loose sand grains together.
