Key Words: Risk Assessment, FACE-CARAS, CAMHS Risk Assessment
Abstract

Background: The FACE-CARAS (Functional Analysis in Care Environments- Child and Adolescent Risk-Assessment Suite) toolkit has been developed to support practitioners in Child and Adolescent Mental Health Services (CAMHS) in performing a structured risk assessment. It covers a number of risk domains including violence, suicide, self-harm, experienced abuse and exploitation. Inter-rater and internal reliability has already been established, but not predictive validity.

Aims / Hypothesis: Our aim was to establish the predictive validity of the FACE-CARAS in a CAMHS population.

Methods: Records from 123 young people with FACE-CARAS ratings completed by clinicians were examined in a retrospective file review to extract data on a relevant list of adverse outcomes at three and at six months following the assessment. Although this was not a prospective longitudinal study, researchers were blind to the clinicians’ ratings, allowing valid testing of predictive power. Cases were drawn from across generic and specialist CAMHS teams in approximately equal proportions. Data were analysed using receiver operator characteristic (ROC) statistics.

Results: Areas under the curve (AUC) values in five of the seven risk areas approached or were greater than 0.8, indicated that the FACE-CARAS profile score was a good potential predictor of risks of self-harm, suicidal behaviours, serious self-neglect, abuse or exploitation by others, and violence to others at both three and six months. It was weakly ‘predictive’ of accidental self-harm and no better than chance at signalling physical ill health.

Conclusions: Findings support the use of the ‘profile summary’ section of the tool as likely to generate clinically useful risk predictions. We were concerned that clinical use of the scale did not conform to research standards, and often left subscales

incompletely rated, however, the fact that the tool nonetheless proved a good
predictor of most key adversities under scrutiny may add weight to its value in clinical
practice. Further work with the FACE-CARAS subscales is recommended.
Background

Risk assessment research in the criminal justice or forensic mental health system has focussed mainly on risk of violence to others. The initial development of tools stemmed from offender classification systems (Blackburn 1993, Quay 1983) and focussed on generating evidence that tools could classify groups of offenders for management and treatment regimes based on specific risk factors. Risk factors are developed from statistical regression, but when applied to young people this creates particular problems as they have had less time to establish patterns of behaviour and because of the biological and social changes continuing to affect their development (Borum and Verhagen 2006).

Tools for systematising assessment of risk of some adverse behaviours during adolescence have been developed, including risk of violence to others (Borum, Bartel and Forth, 2006), of sexually harmful behaviour (Worling, Bookalam and Litteljohn, 2012, and of general offending (Hoge and Andrews, 2002; McGrath and Thompson, 2012). There are fewer tools available to help simultaneously calculate risks to the young person, with attention only to more general risk factors (Posporelis, Paspali, Takayanagi, Sawal, Banerjea, and Kyriakopoulos, 2015). Suicide is rare in adolescence (Windfuhr, While, Hunt, Shaw, Appleby and Kapur, 2013), but it is estimated that 7-14% of adolescents have engaged in deliberately self-harming behaviours (Hawton and James 2005), while accidental or co-incidental self-harm, for example from drug use or reckless driving, is also common.

Within risk assessment research, since 2010, there has been a focus on ‘Field Validity’ (previously referred to as ‘ecological validity’) - or how a risk assessment
tool functions in a real world setting (see Perrault, Vincent, Guy, Ben-Porath, Edens and Boccaccini 2017, Singh and Fazel 2010). This focuses on how tools are used by clinicians and the predictions made function in real world practice. This approach has informed this study.

UK Service Structures

Within UK NHS Child and Adolescent Mental Health Services (CAMHS) there is considerable political pressure on services to reduce time spent waiting for assessment and treatment. This has led to innovations such as the Choice and Partnership Approach (CAPA: National CAMHS Support Service 2009) that focus on streamlining and standardising the ‘patient’s journey’. This creates additional strain on professionals to categorise and predict risk to and from their patients with accuracy. UK NHS mental health services are organised into four tiers, reflecting complexity and level of intervention; those requiring management from mental health services are seen at Tier 3 generic regional CAMHS services. Services with additional specialist input, such as forensic mental health or learning disability psychiatry, are Tier 4.

The FACE (Functional Analysis in Care Environments) organisation developed the Child and Adolescent Risk Assessment Suite (CARAS) to support risk evaluation in CAMHS at the point the young person is first seen. The CARAS is innovative because it supports assessment of a wide range of risks not previously quantified. Although there have been prior attempts to analyse factors linked to adolescent vulnerability (Fischof, Nightingale and Ianotta 2001), these were never brought together into a tool. The toolkit, now adopted by a number of NHS trusts in England,
Scotland, Wales and Northern Ireland. It covers the varied patterns of risk that confront the CAMHS worker and is a two-stage process. The worker must first review a checklist of 48 items and then decide on using one of nine component sub-scales: *self-harm, violence and aggression, vulnerability, risks associated with psychosis and violence, eating disorders, learning disability vulnerability, harmful sexual behaviour, specific management issues in open setting and in secure inpatient settings.* The assessor must rate each item on a scale of 0-3; scales vary in length but include around 20 individual factors. Finally, an overall rating of 0-4 is made for seven risks - of: *violence, suicide, deliberate self-harm, severe self-neglect, accidental self-harm, abuse / exploitation, physical condition.* The anchor points for the scoring of this risk profile and implications for risk management are shown in table 1.

Table 1 about here

The original content for the nine scales was drawn from published literature and findings from a series of focus groups (Daniel, Weir and Tiffin 2013). Subsequent work has established the inter-rater reliability of the scales in a field pilot (Tiffin, Kitchen and Weir 2015) and, in a more limited study, their inter-rater reliability (Evans and Oswald 2017). These studies also provided evidence of content validity. The component scales can be reliably coded and scored, with minimal training, by practitioners. The predictive accuracy of the scales has not, however, previously been established. Our aim, therefore, was to evaluate the predictive accuracy of the summary risk profile scores.
Methods

Ethics

The research protocol received a favourable ethical opinion from the West of Scotland Research Ethics Committee and. The NHS Greater Glasgow and Clyde (NHSGGC) Research Department supported and sponsored the study.

The sample

The sample was drawn from the NHSGGC Children and Young People’s Specialist Services (CYPSS) cover areas across Glasgow and the Clyde Valley. The area served has multiple issues of deprivation (Marryat, Thompson, Minnis and Wilson 2015), with resultant expectations of increased prevalence of adverse childhood experiences (ACES) that, in turn, increase risk of psychiatric morbidity in children (Roberts, Donkin, and Marmot 2016). All included patient records were from service Tiers 3 and 4.

Each team was asked to provide 10 cases which had been open for more than six months following risk assessment using the CARAS. No specific randomisation procedures were applied in selecting cases to be reviewed, but business support staff, who had no direct involvement in the cases, were used to provide case records. In some casenotes, such as when the referral had been solely for a particular assessment, records were too limited determine the presence or absence of behaviours after the assessment date, so these cases were removed from the final sample.

Procedure for Completing the FACE-CARAS by CAMHS Clinicians
The procedure for completion of the FACE-CARAS has been discussed in the introduction. The clinician is expected to complete a checklist of risks after the initial assessment appointments, then select from a group of subscales covering patterns of risk related to; eating disorders, physical aggression, self-harm and suicide, sexually harmful behaviour, vulnerability, and risks for inpatient populations and young people with learning disabilities. From this assessment the clinician determines the ‘risk profile’ - level of risk and risk management in the seven areas discussed.

Procedure Used by Researchers to Examine Accuracy of Prediction

The outcome data was collected from an exhaustive retrospective review of all of the casenotes in existing mental health file records and was completed by the researcher. The presence or absence of risk related behaviours was then recorded under the following categories violence, suicide, deliberate self-harm, severe self-neglect, accidental self-harm, abuse / exploitation, physical condition as either present or absent. A record was made if the behaviour appeared in the first three months following assessment, or in the second three months. If the behaviour was first found in the first three months it was considered met in the second three months. This was then compared against the risk profile score ascribed by the clinician in the original FACE-CARAS Risk Profile Assessment.

Defining outcome

Assessment of the value of a risk assessment tool depends comparing the extent to which a projected outcome is fulfilled by occurrence of a real outcome. The seven projected outcomes are defined by the scale scores, but the seven real outcomes have not previously been strictly defined by the authors of the scale. We therefore
developed criteria for them (see appendix 1). It was impossible to exclude cases where the behaviour was prevented by risk management, there was one completed suicide in the sample but many cases where suicidal behaviours were present but prevented by risk management such as being placed in an inpatient setting or residential care. This created some tautology for these factors: a high risk assessment score was also likely to lead to inpatient care or use of child protection measures however risk management was invariably accompanied by risk related behaviour.

Statistical Analyses

We used receiver operator characteristics (ROC) to determine the significance and size of the effect which, effectively, which yields an ‘area under the curve (AUC), the size of which indicated the range of correct ‘hits’. An AUC of 1 would be perfect, and of 0.5 not better than chance. It is generally accepted that 0.9-1.0 represents excellent prediction, 0.8-0.9 good prediction, 0.7-0.8 fair prediction, 0.6-0.7 weak prediction, and 0.5-0.6 no or little better than chance.

Two sets of scores are available from the tool produced by the risk profile giving a score of between 0-4 for each risk type as noted in the table above and scores from sub-scales used by the clinicians. The risk profiles were used universally, but few sub-scales were completed meaning that any analysis of the sub-scales was impossible. It had been intended to use a sum of scaled scores as a form of analysis of the predictive accuracy of sub-scales. This output research focuses solely on the risk profile scores and no analysis is included of the sub-scales. Statistical support was provided through Strathclyde University.

Results
There were 123 young people for whom at least six months of adequate post assessment data were available. Mean age was 13.5 years (range 5-18 years); but 91 (74%) were 13-18. Eighty-nine of the sample were drawn from the eight regional NHS CAMHS (Tier 3) teams in the greater Glasgow area and 34 were from the three specialist CAMHS teams (Tier 4).

How the scale is used in practice
Sub-scales of the CARAS had often not been completed. According to guidance on use of the scale, a score of ‘2’ on any initial screening risk-profile indicates that a full sub-scale should be completed, but we found that Tier 3 teams had followed this in 25% of cases; among tier 4 teams, relevant subscale completion was higher at 73%. Screened risk scores differed between the two tiers of service, with the Tier 3 services recording a score or 2 or greater in n (38%) of cases and Tier 4 in n (55%) of cases. There was a difference in risk profile scores between Tier 3 and 4 teams, with average risk profile scores significantly distinguishing between the tiers (f-test p<0.05). A similar pattern was observed in relation to multiple risks, with n (3%) of tier 3 cases having more than one risk profile score at 2 or more and n (25%) of tier 4 cases having multiple patterns of significant risk.

Accuracy of Prediction
Table 2 shows that five of the seven risk subscales had a fair to good prediction accuracy; risk of accidental harm was predicted with only modest accuracy. Only the risk related to physical condition scale offered a prediction that was no better than chance. The table also show predictive values for outcomes at 3 and 6 months separately.
There is little difference between the AUC figures at three and six months, but if anything, a tendency for slightly improved prediction in some subscales and minor reduction in some other areas.

In the majority of assessments the accuracy of prediction was heavily influenced by the levels of true negative predictions - where the clinician correctly predicted no risk. Figure 1 shows a distribution effect across the risk categories. The dense grouping at the score 0 denoting absence of risk of adverse events confirms clinicians’ ability to categorise, essentially, safety correctly and that false positives were rare.

**Figure 1 about here**

*Analysis of prediction by score point*

Prediction generally functioned best at values greater than zero and this is evident in the sensitivity and specificity scores shown in table 3. This indicated a reluctance to give high scores, the most commonly assigned rating being ‘1’. While it may be a characteristic of the population in mainstream CAMHS that high risks are largely absent compared to specialist CAMHS, where risky behaviours appeared more frequently, it may be that clinicians are reluctant to produce high risk ratings on the profiles. This may be caused by workload stress and a wish to avoid the increase to the workload from higher risk ratings and related risk management.

*Table 3 about here*
Discussion

We found that CAMHS clinicians were able to use the CARAS to assess a range of seven major risks of harm for the young patients entering their services. Their resultant predictions fell into the good to excellent range in correctly identifying behaviours or events in relation to these young people at three months and at six months after the ratings. The only area of prediction which was apparently no better than chance was related to physical health, but this was an area where significant risks were exceptional and a no risk rating was accurate.

Although AUC statistics compare favourably with other risk assessment tools, it should be remembered that many of the patients are being admitted to Tier 3 services for procedures such as diagnostic assessments and high levels of risk would not normally be expected in these patients. A primary finding is that clinicians are able to differentiate these cases from cases with more obvious patterns of risk. This is a different risk assessment task than determining comparative levels of risk within populations such as released prisoners, or comparative risk of neglect in children in care.

What Type of Risk Assessment is the FACE-CARAS?

Our findings show there is limited adherence to use of the full protocol for use of this scale, with the vast majority of assessments rarely using the subscale sections of the toolkit even when the screen score should trigger such action. This raises a question as to whether the measure is being used for simply recording unstructured professional judgement. There is a risk of this research being drawn into an ongoing controversy around the use and validity of different risk assessment methods.
Cooke and Michie (2013; Hart, Michie and Cooke, 2007) have argued against the validity of actuarial measures in risk assessment of individual cases, valuing the primacy of clinical judgement within the framework of structured clinical/professional judgement tools. This research has led to criticism (Mossman and Selke 2007) and papers that have deconstructed the validity of the statistical measures used by Hart, Michie and Cooke (Scurich and John 2011). Other risk assessment researchers have argued that all risk assessment should be actuarial and that clinical judgement should be routinely distrusted (Harris, Rice, Quinsey and Cormier 2015). Both groups have provided empirical support and argument for their views and largely accept a “scholarly division of opinion” (Harris et al 2015 p184).

It is important to emphasise that the clinicians in this study were forming their judgements using the FACE CARAS toolkit, but largely deviating from the scale protocols. The tool’s structure and training indicate that the clinician should come to a judgement through a two-stage process, first completing a screening checklist of risk factors and then completing relevant sub-scales before coming to a final judgement. In the records assessed it would appear that many were not following up on the sub-scales, but the checklist of common risk factors is enough to anchor the judgments anyway - and is what is achievable within workplace pressures.

The number of judgements being made at this point (48 separate risk factors rated at two time periods) would make it broadly similar to other older established risk assessments used for offender classification namely, the Level of Service Inventory (Andrews and Bonta 1995) and the Youth Level of Service Inventory (Hoge and
Andrews 2002) and places the FACE-CARAS alongside other proven structured professional judgement tools that are anchored by actuarial factors developed for classification of need. The protocol has been adapted by applied clinicians to meet their needs as service providers working under pressure, but still retains accuracy.

**Study strengths and limitations**

There are two significant limitations to this research. The sampling method was created to ensure a database of cases with adequate record keeping rather than using a randomised pattern of case selection. The eventual method of asking support staff rather than case managers to select the cases from the electronic databases prevented cherry picking of cases with optimal outcomes, but we recognise randomisation would have improved the methodology. It should also be noted that, our sample was of patients in the service for at least six months. Thus, our findings may not generalise to more short-term cases. Secondly, as discussed previously there is a tautology in the structures used to determine the outcomes in suicide assessments and risk of abuse and exploitation. Consequently, the clinician can potentially reduce the chance of their own prediction being fulfilled, indeed has a duty to do so, by beginning processes to have the young person placed in hospital or residential care.

Our findings place the findings on accuracy of suicide risk assessment in conflict with recent research in this area that has found clinical judgement (Woodford, Spittal, Milner, McGill, Kapur, Pirkis, Mitchell, and Carter 2017) and risk scales (Chan, Bhatti, Meader, Stockton, Evans, O’Connor, Kapur, and Kendall 2016) to be inaccurate predictors. The primary reason for this is these studies used completed suicide as the criteria for risk being present. Given the extensive legal powers that can
be taken to prevent suicide or impose child protection it is unclear how meaningful this is as a measure as it implies that risk management has broken down possibly indicating a failure in care rather than a characteristic of the patient. Whatever criteria is used will influence the assessment of predictive accuracy, however, if the criteria of competed suicide was to be used in this study the predictive accuracy for this behaviour would be absent.

**Conclusions**

We found that the FACE-CARAS shows good predictive accuracy over a range of risks of harm common in a child and adolescent mental health populations. A strength of our study was that it analysed use of the scale in a real world setting, demonstrating its strengths even when abbreviated by clinicians in practice.

Appendix (online supplement only)

Criteria for Considering Risk Assessment Values

This sets out criteria for considering that risk as predicted is considered true within the three month period following assessment.

Risk of Violence / Harm to Others: An incident involving an attempt to cause physical harm to another, or a sustained period of shouting and denigration a victim involving multiple incidents or acts over the three months. These incidents should have been recorded as a violent incident or be at a level where they could have been recorded as violence by a carer, professional or family member. This also includes sexually harmful behaviour that would be characterised as illegal sexual activity.

Risk of Suicide: An attempt by the person to;
- end their life or,
- continued statements made that they would seek to end their life if they had opportunity n.b. the person must be in a position that opportunity has been removed or restricted such as inpatient care

Risk of Deliberate Self-Harm: An incident where the person engages in self-injurious behaviour such as;
- cutting
- severe pinching or other harm to the skin
- punching themselves to cause bruising
- ingesting substances or objects that require medical intervention

Risk of Severe Self-Neglect: An incident where the person takes action to place themselves at harm such as;
- failing to eat or drink sufficient sustenance
- exposing themselves to extremes of heat or cold without good reason
- failing to seek help for an accidental injury
- rejecting necessary medical or psychological support to a level of endangerment

Risk of Accidental Self-Harm: Being in situations where serious harm could befall them such as;
- risk taking behaviours
- risk related to symptoms of illness such as epilepsy
- not having sufficient awareness or reaction to environmental hazards

Risk of Abuse / Exploitation by Others: Pursuing relationships or having involuntary relationships with others where;
- sexual exploitation such as underage or harmful sexual relationships may have taken place
- the person has been financially exploited
the person has been threatened
the person has been advised not to comply with appropriate and necessary supports
the person has been neglect to a level that would warrant a child protection investigation

**Risk Related to Physical Condition:** The person has an adverse reaction due to the effects of an illness that causes them harm such as;

- Epilepsy
- brain injury
- chronic weight loss
- genetic disorder
- Cerebral Palsy
