Abstract

Atomic nuclei with certain combinations of proton and neutron numbers can adopt reflection-asymmetric or octupole-deformed shapes at low excitation energy. These nuclei present a promising avenue in the search for a permanent atomic electric dipole moment the existence of which has implications for physics beyond the Standard Model of particle physics. Theoretical studies have suggested that certain thorium isotopes may have large octupole deformation. However, due to experimental challenges, the extent of the octupole collectivity in the low-energy states in these thorium nuclei has not yet been demonstrated. Here, we report measurements of the lifetimes of low-energy states in ^{228}Th ($Z = 90$) with a direct electronic fast-timing technique, the mirror symmetric centroid difference method. From lifetime measurements of the low-lying $J^\pi = 1^-$ and $J^\pi = 3^-$ states, the $E1$ transition probability rates and the intrinsic dipole moment are determined. The results are in agreement with those of previous theoretical calculations, allowing us to estimate the extent of the octupole deformation of ^{228}Th . This study indicates that the nuclei ^{229}Th and ^{229}Pa ($Z = 91$) may be good candidates for the search for a permanent atomic electric dipole moment.

Bohr and Mottelson interpreted observed spectra of deformed atomic nuclei as the manifestation of rotational and vibrational degrees of freedom [1, 2]. In this pioneering work, the excitations were understood as rotational or vibrational modes of quadrupole deformed axially-symmetric nuclei. Since then it has become clear that some nuclei may also adopt reflection asymmetric shapes, such as those resulting from long-range octupole-octupole residual interactions. The operator associated with such interactions has negative parity, which leads to the nucleus adopting shapes where reflection symmetry is broken. The distinctive shape associated with static octupole deformation has led to such nuclei being referred to as pear shaped, where the nuclear density is higher at one pole than the other. Such octupole deformation can result in a separation of the centres of charge and mass which can result in a sizeable electric dipole ($E1$) moment, which will be observable through enhanced $E1$ transitions between nuclear states [3].

Reflection asymmetric nuclei have attracted attention in recent years in the search for a permanent atomic electric dipole moment (EDM). The Standard Model predicts a vanishingly small, but non-zero, EDM. To date, no evidence has been found that supports this prediction, despite several experiments having been undertaken using different methods [4–8]. This is because the EDM predicted by the Standard Model is far below the sensitivity of current experimental capabilities. Nevertheless, by placing upper limits on an EDM, these studies have successfully constrained any proposed extensions of the Standard Model predicting a significantly larger EDM value. The ACME II experiment, which has recently improved on the upper limit on the EDM value by an order of magnitude [8], involves laser spectroscopy of thorium monoxide molecules to measure the EDM. Some isotopes of thorium are predicted to exhibit an enhanced octupole collectivity at low excitation energies [9]. The use of such nuclei in the search for an EDM would be particularly attractive because the induced $E1$ moment resulting from the reflection asymmetric shape enhances the nuclear Schiff moment [10–13], and therefore the atomic EDM, by two to three orders of magnitude [14, 15]. In particular, Ref. [14] shows that the Schiff moment in the laboratory frame exhibits a quadratic dependence on the extent of the octupole deformation.

One nucleus identified early as an ideal candidate with which to search for an EDM is ^{229}Pa ($Z = 91$). Possessing an odd number of protons, this nucleus was predicted to have a low-lying parity doublet in which two states with the same total angular momentum are found almost degenerate in energy [16]. Such a doublet, which is regarded as a signature of octupole

correlations, was first reported by Ahmad *et al.* [17] in 1982. More recently, however, doubt has been cast upon the existence of this doublet due to a lack of conclusive evidence [18–20]. Should ^{229}Pa indeed be octupole deformed in the ground state it is expected that the even-even nucleus ^{228}Th ($Z = 90$), which constitutes the core of ^{229}Pa to which an unpaired proton is coupled, would also exhibit characteristics consistent with enhanced octupole correlations. Another nucleus where an enhanced nuclear Schiff moment is predicted is thorium-229, which corresponds to an unpaired neutron coupled to a ^{228}Th core [21]. This further emphasises the importance of determining the octupole deformation in ^{228}Th .

A signature of reflection asymmetry in even-even nuclei is the presence of low-lying negative parity states. Such states, with total angular momentum values corresponding to $1 \hbar$ and $3 \hbar$, were first identified in α -decay spectroscopy measurements in the 1950s [22, 23]. Electromagnetic transitions between these negative parity states and members of the ground state band are also good indications of octupole collectivity. For instance, the observation of enhanced electric octupole ($E3$) transitions between the low-lying $J = 3^-$ state and the $J = 0^+$ ground state is considered as an unambiguous signature of octupole collectivity [24]. To date only two known nuclei have been found to exhibit both signatures: ^{224}Ra [25] and ^{226}Ra [26]. Nevertheless, there are several actinide nuclei that have low-lying negative parity states; theoretical studies have suggested they should have appreciable octupole deformations in the ground state [9, 27]. Indeed, density functional theories used in Ref. [9] suggest that thorium nuclei are likely to have the largest octupole deformations of all the actinides. However, disagreement exist between different theoretical models on which thorium nucleus should exhibit the largest octupole collectivity. In the work of Agbemava *et al.* [9], pronounced quadrupole and octupole deformations are expected in the ground states of ^{226}Th and ^{228}Th and the octupole deformation parameter β_3 is maximised for the latter. In this paper we investigate the extent of octupole collectivity in ^{228}Th by measuring the enhancement of electric dipole transitions from the low-lying $J = 1^-$ and 3^- states.

The observation of enhanced $E1$ transitions connecting negative and positive parity states is generally considered a good indication of reflection asymmetry, albeit with some ambiguity [3, 28]. One source of ambiguity arises from the enhancement of electric dipole transitions that are not unique to octupole deformed nuclei but also manifest in well-deformed reflection-symmetric nuclei due to the presence of low-lying octupole vibrational states [28]. This is further complicated because the microscopic shell contribution to the dipole moment in the

intrinsic frame effectively negates the macroscopic contribution from the reflection asymmetric shape of the nucleus, which was first identified by Butler and Nazarewicz [3]. The most striking example of this is observed in the work of Gaffney *et al.* [25] where they reported measurements of a large $E3$ strength in ^{224}Ra . This indicates a sizeable octupole collectivity in the ground state, yet a small $E1$ strength, consistent with reflection-symmetric nuclei, was also reported.

In our study we measure the lifetimes of low-lying excited states of ^{228}Th using electronic fast timing techniques based on fast scintillating γ -ray detectors. This represents the first measurement of the absolute electric dipole transition rates in any thorium isotopes, for the low-lying negative-parity states characteristic of octupole collectivity. When compared with calculations available in the literature [24] we conclude that the low-energy structure of ^{228}Th is consistent with a strongly quadrupole-deformed nucleus with an octupole deformation comparable with that reported in ^{224}Ra [25]. Our findings suggest that the odd- A nuclei ^{229}Th and ^{229}Pa may be good candidates with which to search for a permanent EDM.

Spectra of γ radiation detected with the Start LaBr₃(Ce) and HPGe detectors are shown in Figure 1. The definition of the detectors can be found in the Methods section of this paper. Since data are only recorded when a TAC pulse is generated, the LaBr₃(Ce) spectrum of Figure 1 represents the projection of a two-dimensional $\gamma - \gamma$ (or Start-Stop) coincidence matrix. The HPGe spectrum, however, is the projection of a three-dimensional $\gamma - \gamma - \gamma$ (Start-Stop-HPGe) coincidence matrix. It is clear from the spectrum that the majority of the γ radiations observed is the result of decays of excited states in ^{208}Pb ($Z = 82$) and ^{228}Th . The former is the result of the β -decay of ^{208}Tl ($Z = 81$) as the final stage of the ^{232}Th decay chain, while excited states of ^{228}Th are populated as the result of β -decay of ^{228}Ac ($Z = 89$). There are a few intense γ rays associated with the ^{232}Th decay chain that are not observed in the spectra of Fig. 1 due to the decays having unity multiplicity and, therefore, do not generate a TAC output.

The excited states and γ -ray transitions of interest in ^{228}Th are shown in Figure 2. To measure the lifetime of the $J^\pi = 1^-$ state, the time difference between the arrival of 795 keV and 328 keV or 795 keV and 270 keV transition photons (as they populate and depopulate the state, respectively) was measured with the TAC. Corresponding TAC spectra are shown in Figure 3a while a sample of the γ rays observed in coincidence with the 795 keV transition is presented in Figure 3c. Peaks corresponding to the 270 keV and 328 keV transitions de-

FIG. 1: Gamma-ray spectra resulting from the decay of ^{232}Th . The top panel shows γ radiations detected with the Start $\text{LaBr}_3(\text{Ce})$ detector in coincidence with radiation detected in the Stop $\text{LaBr}_3(\text{Ce})$ detector. The bottom panel shows the γ -ray spectrum detected with a high-purity germanium detector in coincidence with γ rays detected in both the Start and Stop detectors. Peaks labelled in black and red are associated with the decay of excited states in ^{228}Th and ^{208}Pb , respectively.

FIG. 2: A partial level scheme showing relevant states and γ -ray transitions in ^{228}Th . The total angular momentum and parity of each state is indicated on the left for states of positive parity and right for negative parity. The γ -ray transitions are indicated by vertical arrows with the corresponding energy in units of keV shown.

exciting the 1^- state clearly dominate the spectrum of Fig. 3c. In addition, some background peaks corresponding to other intense transitions in the ^{232}Th decay chain can be observed. As a result, the peaks of interest for lifetime measurements sit on top of a background dominated by events corresponding to Compton scattered background γ rays. The method outlined by Ansari *et al.* [29] has been employed to correct for the effect of this background. Following correction, the lifetime of the $J^\pi = 1^-$ state was measured to be $\tau = 4(3)$ ps with the 795-328 keV combination. Using the 795-270 keV combination it was only possible to measure an upper limit corresponding to $\tau \leq 5$ ps. This value is consistent with the lifetime measured with the 795-328 keV combination but has likely been affected by the presence of

FIG. 3: Timing and γ -ray energy spectra. **a** Time-to-amplitude converter (TAC) spectra showing delayed and anti-delayed coincidences between 795 keV and 328 keV transitions populating and depopulating the $J^\pi = 1^-$ state; **b** similar to **a** but for the 772 keV and 338 keV transitions populating and depopulating the $J^\pi = 3^-$ state; **c** spectrum of γ rays in coincidence with 795 keV transition feeding the $J^\pi = 1^-$ state; **d** γ rays in coincidence with 772 keV transitions feeding the $J^\pi = 3^-$ state. In panels **c** and **d**, the peaks labelled in black are associated with γ -ray transitions in ^{228}Th .

an intense 277 keV transition in the decay of ^{208}Pb [30] the influence of which cannot be excluded.

Figure 3d shows γ radiations observed in coincidence with 772 keV transitions which feed the $J^\pi = 3^-$ state. The 209 keV and 338 keV transitions, which have been established to deexcite the 3^- state, dominate this spectrum in addition to some background peaks. The 209 keV peak is significantly wider than that at 338 keV (and indeed the 270 keV peak in Fig. 3c) suggesting the presence of additional background. It is likely that this is due to backscattered photons originating from the other nearby detectors. The TAC spectra corresponding to the 772 keV feeder and the 338 keV decay transitions are shown in Fig. 3b. The background-corrected lifetime for the 3^- state is found to be $\tau = 13.2(23)$ ps. In addition to the lifetimes of the low-lying negative parity states, lifetimes of three positive-parity states have been measured and listed in Table I.

The lifetimes of the first $J^\pi = 2^+$ and 4^+ states have previously been measured using the delayed-coincidence technique, where the difference in time between detection of a populating α particle and the de-exciting γ -ray was measured [32]. Our results are in good agreement

TABLE I: Properties of levels and transitions in ^{228}Th as measured in this work. The first three columns list the excitation energies, the total angular momenta and parities and the measured lifetimes. The remaining columns list the reduced transition probabilities, $B(EL)$, and the intrinsic electric dipole, D_0 , and quadrupole moments, Q_0 . To calculate the reduced transition probabilities, data related to the branching ratios, internal coefficients and transition multipolarities have been extracted from Ref. [31].

E_{level} [keV]	$J_i^\pi \rightarrow J_f^\pi$	τ [ps]	$B(E1)$ [10^{-4}W.u.]	$ D_0 $ [efm]	$B(E2)$ [W.u.]	$ Q_0 $ [efm ²]
58	$2^+ \rightarrow 0^+$	587(12)			170(3)	840(17)
187	$4^+ \rightarrow 2^+$	260(14)			224(12)	808(44)
328	$1^- \rightarrow 0^+$	4(3)	8(6)	0.16(8)		
328	$1^- \rightarrow 2^+$	≤ 5	≥ 14	≥ 0.14		
396	$3^- \rightarrow 2^+$	13.2(23)	3.8(7)	0.09(2)		
969	$2^+ \rightarrow 2^+$	3.8(21)			2.5(14)	
969	$2^+ \rightarrow 0^+$	3.8(21)			1.1(6)	

with these studies confirming a large quadrupole deformation in the ground state. We have also measured the lifetime of the $J^\pi = 2^+$ state for an excitation energy of 969 keV. Previous studies of the high-spin states of ^{228}Th have identified the state as the bandhead of a $K^\pi = 2^+$ γ -vibrational band [33]. The reduced transition probability, $B(E2; 2_\gamma^+ \rightarrow 0^+) = 1.1(6)$ W.u., is similar to the $B(E2; 2_\gamma^+ \rightarrow 0^+) = 1.3(5)$ W.u. value measured by Gaffney *et al.* [25] for the γ -vibrational bandhead in ^{224}Ra . In addition, the $\frac{B(E2; 2_\gamma^+ \rightarrow 0^+)}{B(E2; 2_\gamma^+ \rightarrow 2^+)} = 0.45(29)$ ratio is consistent, within uncertainties, with the limit of 0.7 expected from the Alaga rules [34], which further supports the assignment of this level as the γ -vibrational bandhead in ^{228}Th .

The measured lifetime of the $J^\pi = 1^-$ state allows for a $B(E1; 1^- \rightarrow 0^+) = 0.8(6) \times 10^{-3}$ W.u. value to be extracted. A $B(E1)$ rate of this magnitude is consistent with enhanced octupole collectivity, but is similar to the $B(E1; 1^- \rightarrow 0^+) < 1.5 \times 10^{-3}$ W.u. value reported by Gaffney *et al.* [25] for the octupole-vibrating nucleus $^{220}_{86}\text{Rn}$. Few theoretical predictions exist for the $E1$ strength of low-energy states of the thorium nucleus. A comprehensive study of the dipole strength in actinide nuclei, performed by Butler and Nazarewicz [3], predicts the $E1$ strength only for the high-spin states of ^{228}Th . A more recent study, performed by

Robledo and Butler [24], considered the coupling of the quadrupole and octupole collective degrees of freedom to predict $B(E1; 1^- \rightarrow 0^+) = 1.2 \times 10^{-3}$ W.u. for ^{228}Th .

The intrinsic dipole moment, D_0 , can be calculated directly from the measured $B(E1)$ rates according to the rotational model formula:

$$B(E1; J_i \rightarrow J_f) = \frac{3}{4\pi} D_0^2 \langle J_i K_i 10 | J_f K_f \rangle^2, \quad (1)$$

where $\langle J_i K_i 10 | J_f K_f \rangle$ is the Clebsch-Gordan coefficient. The use of a rotational model formula is appropriate for a nucleus such as ^{228}Th , which exhibits clear signs of rotational motion ($Q_0 = 840(17)$ efm² and $E(4_1^+)/E(2_1^+) = 3.22$). This formula is commonly applied to the actinide region, regardless of how rotational the nuclei appear, to obtain a consistent measure of the dipole moment from available data. Our measurement results in a value of $D_0 = 0.16(8)$ efm for the $J^\pi = 1^-$ state. This D_0 value, while consistent within one standard deviation, is larger than the values reported for any of the higher spin states of ^{228}Th extracted indirectly from observed $B(E1)/B(E2)$ ratios [35, 36]. This dipole moment is also larger than the prediction of $D_0 = 0.07$ efm for $J^\pi = 8^-$ by Butler and Nazarewicz [3] indicating that the dipole moment, and possibly, the octupole collectivity in this nucleus was underestimated in their calculations.

The intrinsic dipole moment of $D_0 = 0.09(2)$ efm calculated in the current work for the $J^\pi = 3^-$ state in ^{228}Th is consistent with the results of Ackermann *et al.* [36] in which a lower limit ($D_0 \geq 0.1$ efm) was determined by means of $B(E1)/B(E2)$ ratios. The lower limit in the previous study corresponds to a maximum value of the observed branching of the $3^- \rightarrow 1^-$ $E2$ transition. It is worth noting that the value of D_0 measured for the $J^\pi = 3^-$ state in our work is in good agreement with the values established for higher-spin states in the octupole band of ^{228}Th which range from 0.11 – 0.13 [35, 36].

The fact that the calculations of Robledo and Butler [24] reproduce the experimentally-determined $B(E1; 1^- \rightarrow 0^+)$ value suggests that they can be used to estimate the extent of octupole collectivity in the low-energy states of ^{228}Th . In the case of the ground state of ^{228}Th , the calculations of Ref. [24] predict a pronounced minimum in the potential energy corresponding to an octupole moment $Q_3 = 3500$ efm³. These calculations overestimate the octupole moment in ^{224}Ra , which was measured to be $Q_3 = 2520(90)$ efm³ [25], by a factor of $\sim 15\%$. Scaling the octupole moment for ^{228}Th to 2950 efm³ and using the measured quadrupole moment $Q_0(2^+) = 840(17)$ efm², the equations described by Leander and

Chen [37] have been used (neglecting terms higher than $L = 3$) to calculate the quadrupole and octupole deformation parameters $\beta_2 = 0.21(1)$ and $\beta_3 = 0.11(2)$ for ^{228}Th . The uncertainties reported here include the effects of measurements and the scaling factor in the octupole moment. These values of the deformation parameters are comparable with the theoretical values of $\beta_2 = 0.21$ and $\beta_3 = 0.15$ reported by Agbemava *et al.* [9]. Dobaczewski *et al.* [38] have predicted that the Schiff moments of odd- A actinide nuclei are correlated with the octupole moments in the neighbouring even-even nuclei. Comparing the octupole deformation obtained as a result of this work with those reported for ^{224}Ra [25] ($\beta_2 = 0.154$ and $\beta_3 = 0.097$) indicates that odd- A nuclei composed of a ^{228}Th core, such as ^{229}Pa and ^{229}Th , may be superior candidates for the search for a nuclear EDM. The increased β_3 value for ^{228}Th means that the collective Schiff moment may be larger in ^{229}Pa and ^{229}Th compared with odd- A Rn and Ra nuclei currently attracting attention in searches for an atomic EDM [39, 40].

Excited states of ^{228}Th are populated by the β -decay of the ground state of $^{228}_{89}\text{Ac}$ following the α -decay of the ^{232}Th nucleus. A foil of natural 99.5% purity thorium with dimensions of $50 \times 50 \times 0.05$ mm acted as a source of ^{232}Th nuclei with an activity corresponding to approximately 6 kBq. Due to being in a state of secular equilibrium the foil provided ~ 6 kBq of ^{228}Ac . The thorium foil was located equidistant between two cerium-doped lanthanum bromide ($\text{LaBr}_3(\text{Ce})$) detectors, the front faces of which were separated by 7 mm. The thorium foil was oriented such that short axis was aligned along the $\text{LaBr}_3(\text{Ce})$ - $\text{LaBr}_3(\text{Ce})$ detector axis. This arrangement ensured that the difference in distance between a decaying nucleus and each of the $\text{LaBr}_3(\text{Ce})$ detectors remains less than 0.05 mm at all times. This ensured that any offsets in the time spectra were reduced to below 0.2 ps. The cylindrical $\text{LaBr}_3(\text{Ce})$ crystals each had a diameter and length of 25.4 mm and are coupled to Hamamatsu R9420 photomultiplier tubes. Each detector was located 3.5 mm from the thorium foil. An Ortec GEM P-type high-purity germanium (HPGe) detector was orientated 90° relative to the $\text{LaBr}_3(\text{Ce})$ - $\text{LaBr}_3(\text{Ce})$ detector axis. This detector had a relative efficiency of 59% and an endcap diameter of 70 mm. Signals from the $\text{LaBr}_3(\text{Ce})$ detectors were optimised for timing measurements and connected to a time-to-amplitude converter (TAC), which produced an output voltage proportional to the difference in time between detection of two detected γ -ray photons, respectively.

Waveform traces from each of the detectors and the TAC were recorded using a CAEN

FIG. 4: Top shows the $\gamma - \gamma$ time-walk dependence with γ -ray energy of the fast-timing apparatus. Data points correspond to transitions depopulating prompt states in ^{152}Sm and ^{152}Gd following the β -decay of ^{152}Eu . Error bars are smaller than the symbols for the data points. Bottom shows the differences between the data and the fitted prompt response function with the dashed line indicating two standard deviations.

V1725 digitiser and stored using the MIDAS data acquisition software [41]. Custom software was used to reduce the data by extracting the pulse heights from the traces using a moving window deconvolution algorithm. The reduced data were subsequently analysed using the Root data analysis framework [42].

The lifetimes of excited states were measured according to the mirror symmetric centroid difference (MSCD) method outlined by Regis *et al.* [43]. This method involves two γ -ray detectors, the signals of which are processed by a constant-fraction discriminator (CFD). The resultant logic signal from one CFD is used as the Start input of the TAC while the other is artificially delayed before providing the Stop signal for the TAC. The method involves using the Start detector to detect the γ -ray photons populating an excited state of interest and the Stop detector to detect γ rays depopulating the state. As a result, a spectrum of TAC values with a Gaussian distribution is obtained when the lifetime of the state is sufficiently short ($\tau \leq 150$ ps). For longer lifetimes the Gaussian distribution has an exponential tail. This configuration is known as the delayed configuration. In the anti-delayed configuration the Start detector is used to detect the depopulating transition while the Stop detects the populating transition. The difference between the first moments of the delayed and anti-delayed TAC spectra (ΔC) is proportional to the lifetime of the state. However, a natural ‘time-walk’ is associated with the CFD, which must be accounted for to obtain

accurate lifetimes. The effect of the time-walk is such that ΔC values will increase as the energy of the detected transitions increases regardless of the lifetime of the state. The time-walk can be quantified by measuring ΔC as a function of energy for precisely known picosecond transitions. There are a number of suitable states in the ^{152}Sm and ^{152}Gd nuclei that are populated as a result of the β -decay of a standard ^{152}Eu γ -ray calibration source. The resulting ΔC values obtained using the prompt states in ^{152}Sm and ^{152}Gd are shown in Extended Data Figure 1 as a function of the energy of the depopulating transition. The resulting curve fitted to the ^{152}Eu data is known as the prompt response function (typically referred to as PRD) of the fast-timing apparatus, which is used to correct for the CFD time-walk. The lifetime is calculated as $\tau = (\Delta C - \Delta PRD)/2$, where ΔPRD is the difference between PRD values for the γ -ray energies detected with the Start and Stop detectors, respectively. To check that the PRD curve obtained with the ^{152}Eu calibration source remained valid for the thorium foil, measurements of lifetimes of excited states in other nuclei, also populated in the decay of ^{232}Th , have been performed and compared with literature values. For example, the first excited state in ^{212}Po was measured to have a lifetime of 19.5(25) ps which agrees with the value of 20.5(26) ps reported by Kocheva *et al.* [44]. In addition, the lifetime of the second excited state ($E_{\text{level}} = 3198$ keV; $J^\pi = 5^-$) in ^{208}Pb was measured as 443(2) ps in good agreement with the error-weighted literature value of 424(22) ps [30].
