Abstract

Analysing the fluid dynamic performance of a bare rotor when succumb to yawed flow conditions has consistently presented a diminishment in mechanical power conversion efficacy. Introducing a duct along the rotor perimeter has been acknowledged to sustain performance, yet the causation behind this phenomenon is uncertain. This study puts forward an investigation into the hydrodynamic performance concerning a true-scale, ducted, high-solidity tidal turbine in yawed free-stream flows by utilising blade-resolved, unsteady computational fluid dynamics. Investigating the performance within an angular bearing range of 0° to 45° with the turbine axis, increases in mechanical rotational power and thrust are acknowledged within a limited range at distinct tip-speed ratio values. Through the multiple yaw iterations, the maximum attainment falls at an angle of 23.2° , resulting in a power increase of 3.44% to a peak power coefficient of 0.35 at a nominal tip-speed ratio of 2.00, together with an extension of power development along higher tip-speed ratios. In verification of the power increase, the outcomes are analysed by means of linear momentum theory; by utilising area-averaged values of static pressure acquired from annular radial surfaces fore and aft of the rotor, an analogous relationship with the blade-integrated outcomes is attained. The analysis concludes that, at higher tip-speed ratios, the pressure drop across the rotor increases at limited flow bearings, enhancing the resultant axial force loading upon the blades, hence providing further performance augmentation of the ducted, high-solidity tidal turbine.

Keywords: turbine performance, yawed flow, high solidity, open centre, tidal turbine, ducted tidal turbine, RSM

1. Introduction

Efforts to improve upon the efficacy of energy-generating turbines have been in development following global market implementation. At the forefront of the pertinent research are efforts to increase mass-flow through the rotor, sustain power generation in yawed flow conditions, and augment wake flow to facilitate further turbine installations [1]. From the research attained, bi-directional ducts have been installed around a turbine rotor for performance enhancement as a result of the acceleration of axial flow velocity through the duct throat due to the induced Venturi effect and pressure discrepancy between the inlet and outlet. The system has been regarded to maintain axial flow velocity through the duct when succumb to yawed flow, thereby sustaining the performance of a rotor [2, 3, 4]. Yet, despite the potential improvements, the performance capacities of a bi-directional ducted rotor within yawed flow conditions are inadequately understood.

Few research ventures have tackled investigating the fluid dynamics of a duct-feature implementation in a turbine system within misaligned flow conditions [2, 3, 4, 5]. Establishing free-stream bearing variations ranging from $\pm 15^\circ$ to $\pm 60^\circ$, the analyses have concurred the enhancement of generated power as a result of a ducted rotor being succumb to a flow bearing, limited to a definitive yaw angle. Explicit evidence of the circumstances inducing the augmentation, however, has not been consistent. Igra [4] argued that the limited increase was directly associated with the lift produced by the aerofoil cross-section properties of the shroud. Phillips [5] claimed the improved performance was attributed to the slotted diffuser design, which injected pressurised flow from the free-stream for boundary-layer control along the diffuser interior. Albeit the advantageous results from the studies, the validity of the outcomes have been disputed due to uncorrected blockage effects of the structures within the testing facilities. More recent investigations upon tidal turbine systems similarly presented power augmentation, yet forms of methodological limitations had been portrayed, such as discretising the blade structure into elements [6, 7], rather than portraying its true physicality, or undefining the physical effects behind the resultant variation in rotor performance [8].

Evidence of rotor performance enhancement when installed within a shroud has been proclaimed within several decades of research disseminated from pioneering analytical [9] and experimental [2] investigations. The thrust and power generated are enhanced due to the increased dynamic loading upon the rotor as a result of the pressure drop augmentation through the duct. In defining the efficiency of the structure, analytical investigations have indicated that the power enhancement is instigated dependent on the diffuser arrangement and configuration. Cylindrical bi-directional ducts have been established to exhibit no performance improvements once the duct exit area is considered [9]. The flow along the turbine frontal area is directed through the rotor at the throat as a result of the low-pressure region developed immediately downstream. The power per rotor area is increased by a factor equivalent to the duct-to-rotor area ratio. In contrast, ducted turbines with a non-unity inlet to outlet area ratio, hence uni-directional, have been deduced to establish a peak power coefficient of 1.96, equivalent to a 3.3 augmentation factor magnitude higher than the Betz limit [10]. This is attained due to the degree of flow drawn in from a greater area upstream

43 than that interacted by a similarly-sized rotor in open flow.

44 Attributable to the potential augmentation in power extraction as a result of the increase
45 in mass-flow, several commercial endeavours had adopted ducted turbine technology to
46 achieve economic prospects. Amongst the ventures, DCNS/OpenHydro Ltd. had designed
47 an open-centre ducted design approach [11, 12]. In open-water trials, a 2 MW turbine
48 was successfully installed in the Bay of Fundy, Canada, together with a pair of 500 kW
49 rated capacity turbines, as a demonstration array in Paimpol-Bréhat, Northern France, in
50 collaboration with EDF France.

51 Experimental investigations have established the variation in mass-flow and fluid-structure
52 interaction parameters by means of vacant, disc-embedded, and rotor-embedded shrouds.
53 The analyses acknowledged the axial velocity and static pressure drop enhancement through
54 the duct [2, 13]. Further performance enhancement was attained by means of minor compo-
55 nents, notably flapped ring wings and boundary layer control auxiliary slots [14, 15, 16], in
56 accompaniment to a diffuser within aligned and yawed flows. In acknowledging the effect of
57 yawed flow upon the duct, an increase in power generated has been established at distinct
58 angles, with performance sustainment at up to $\pm 30^\circ$ [17, 18]. The outcome was present
59 equivalently present at both positive and negative bearings in relation to the variation of
60 resultant angle-of-attack at the rotor blades [8, 19]. These outcomes distinguish from bare
61 rotor analyses at yawed flow, which have depicted a diminishment in power output [20].

62 Numerical analyses have replicated experimentation, yet instated a multitude of para-
63 metric variations, together with more holistic data acquisition, due to ease of domain ma-
64 nipulation. Implementing a momentum sink within a computational fluid dynamic model
65 has mirrored actuator disc theory and disc-embedded experimentation [21, 22, 23]. Similar
66 drawbacks have, however, been brought about with the absence of radial load distribution
67 and swirl in the rotor wake. Successful validation to experimentation [24] and evidence of
68 performance enhancement, moreover at yaw angled free-stream bearings [25], has been at-
69 tained [26, 27]. In overcoming the detriments of area-averaged disc modelling, blade-element
70 momentum theory has been coupled to the computational domain in analysing yawed flow,
71 acknowledging an increase in resultant power [6, 28]. Furthermore, rotor-explicit analyses
72 have been undertaken, yet have utilised a relative velocity formulation of the governing
73 equations, predominantly implementing a segment of the turbine, rather than a transient
74 rotational sequence [29, 30, 31, 32].

75 The potential rotor power enhancement at a free-stream flow bearing variation with the
76 turbine axis, and its causation, is of particular interest. The performance of a vacant, bi-
77 directional, open-ended, true-scale duct succumb to variable conditional parameters within
78 yawed flow conditions has been analysed [33]. The outcomes presented a 4.08% increase in
79 axial velocity through the duct throat. However, the implementation of a high-solidity rotor
80 with an open-centre within the duct shall induce variant pressure and velocity gradients. The
81 resultant performance of the ducted turbine, as a result of the fluid-structure interaction, is
82 therefore uncertain.

83 The numerical analysis elaborated in this present study has put forward a continuation
84 of Borg et al. [33, 34, 35]. Primarily, a real-scale computational fluid dynamic model was de-
85 veloped to assess the hydrodynamic performance of a high-solidity open-centre rotor within

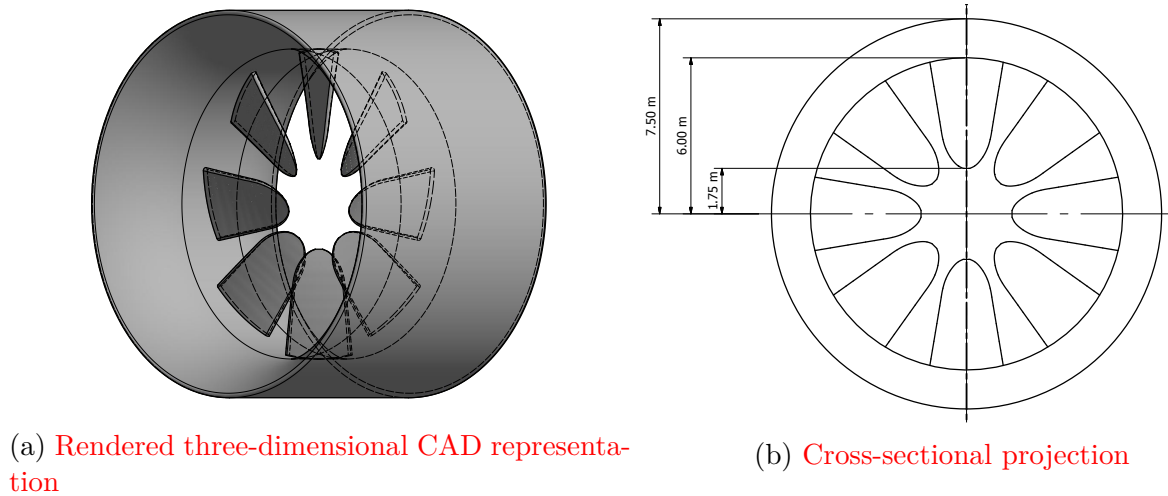

Figure 1: Geometrical model of the ducted tidal turbine [34]

86 a bi-directional duct in aligned flow conditions. Validation of the CFD model for tidal tur-
 87 bine applications was acquired [34]. Additionally, the numerical outcomes of the full-scale
 88 ducted turbine in aligned flow conditions were attained and compared to literature [36] and
 89 blade-element momentum theory [37].

90 In recognition of the variance in tidal stream direction at flood and ebb [38, 39], this
 91 investigation strived to overcome the related limitations by implementing a numerical anal-
 92 ysis with blade-resolved actuality. The individual blades, rather than an area-averaged disc,
 93 were hence established. This permitted three-dimensional flow modelling of the turbine do-
 94 main, together with induced turbulence effects. The aim of this research was to analyse
 95 the hydrodynamic performance of a ducted, high-solidity tidal turbine within yawed flow
 96 conditions, and pinpoint the causation of the performance augmentation. By means of this
 97 investigation, the variation in rotor performance at distinct bearings was acknowledged to
 98 establish the nominal flow-stream parameters. Area-averaged static pressure and axial ve-
 99 locity properties within the duct were acquired to verify and elaborate the outcomes by
 100 means of linear momentum theory.

101 2. Numerical Methodology

102 2.1. Physical Setup

103 As elaborated in Borg et al. [34], to attain a validated CFD model for tidal turbine appli-
 104 cations, simulations were established to numerically replicate experimentation undertaken
 105 by Mycek et al. [40]. Identical blade, nacelle, and mast geometry were utilised within the
 106 model domain, illustrated in Figure 3, onto which a tetrahedral mesh was imprinted. The
 107 general dimensions of the turbine include a diameter D of 0.7 m, a nacelle length of 2.5 m,
 108 and a mast length of 1 m; supplementary descriptions may be attained within the literature.
 109 A distinction is present, however, between the physical aspects of the experimentation and

(a) Flow bearing orientation along turbine section

(b) Data acquisition planar annular surfaces in relation to rotor

Figure 2: Notation of incoming flow bearing in relation to rotor axis & positions of data acquisition planar annular surfaces

110 the numerical model. In the prior, the nacelle mast protrudes through the free-surface to
 111 connect to the above support, whereas, in the latter, only the submerged length of the mast
 112 is considered, with a hemisphere at the tip to avoid tip-induced vortices. Hence, a physical
 113 assumption is present within which the drag forces on the mast are solely considered to be
 114 due to the current, rather than any additional wave & wind factors. Albeit, due to the fact
 115 that waves were not induced in the experimentation, and that the setup was in a closed
 116 environment, the assumption that free-surface and topside effects were insignificant when
 117 considering the induced physics of the turbine was held. The parameters of the turbine and
 118 fluid flow were also instated from the literature, with a constant free-stream velocity of 0.8
 119 m/s, a tip-speed ratio (TSR) range of 1.00 - 8.26, an inlet turbulent length scale of 1 m, and
 120 an inlet turbulence intensity of 3%.

121 In representation of the ducted high-solidity turbine, the model dimensions described
 122 a duct diameter (D) of 15 m, a rotor diameter (D_{rtr}) of 12 m, a hub diameter (D_{hub}) of
 123 3.5 m, and a duct length (L_{dct}) of 10 m, as illustrated in Figure 1. The hydrofoil sections
 124 comprising the rotor blades consisted of a flat-plate design with rounded edges. The external
 125 hydrofoil geometry was quasi-identical to Allsop et al. [41], yet adapted to attain a more
 126 homogeneous blade surface. The geometry was provided by EDF R&D to replicate the
 127 outcomes of a turbine similar to the design of the OpenHydro PS2 device.

128 The domain parameters were instated from real-world data as reported in Neill et al. [42]
 129 and Bahaj and Myers [43], which described maximum acquired spring tide velocities of 4.0
 130 m.s⁻¹ and surface velocities of 5.0 m.s⁻¹, respectively. In addition, Pham and Martin [38] and

131 Pham and Pinte [39] conducted numerical models to simulate the tidal cycle at the Paimpol-
 132 Bréhat site. An asymmetric velocity was acknowledged in both magnitude and direction,
 133 at ebb and flood, with an average-depth angular discrepancy of 20° . For this reason, a
 134 free-stream velocity of $4.0 \text{ m}\cdot\text{s}^{-1}$ was implemented within a yaw bearing (γ) angular range
 135 of 0° to 45° . The bearing range was analysed in iterations of 15° , in addition to a bearing
 136 of 23.2° , which was equivalent to the geometrical gradient of the inlet rim, incoming from
 137 the turbine port direction, as illustrated in Figure 2a. An inlet turbulence intensity of 3%
 138 and an inlet turbulent length scale of 1 m were instated. Within this free-stream variation,
 139 a turbine tip-speed ratio (TSR) range of 1.00 - 2.50 was considered.

140 *2.2. Computational Setup*

141 Correspondent to Borg et al. [34], the numerical model was designed to be a fully sub-
 142 merged system within a constant fluid flow. Far-stream effects from the free-surface and
 143 seabed were therefore abdicated. This setup permitted the performance analysis of the
 144 ducted turbine under consistent temporal conditions. The commercial solver ANSYS Flu-
 145 ent 19.2 was utilised in computing the continuity and Navier–Stokes equations. An Un-
 146 steady Reynolds-averaged Navier–Stokes (URANS) turbulence model was implemented in
 147 mathematical closure to represent flow property fluctuation within the three-dimensional,
 148 unsteady, incompressible flow field.

Figure 3: Rendered three-dimensional CAD representation of the horizontal-axis tidal turbine [40] utilised for the validation of the CFD model [34]

(a) Layout of the ducted turbine domain

(b) Geometric tessellation of the mesh on the duct and rotor blades

Figure 4: Representation of the domain and turbine mesh [34]

149 Establishing a cuboidal domain layout, a cross-sectional quadratic-face edge-length of
150 $7D$ was utilised. The ducted turbine was positioned at the centre of the vertical plane.
151 The dimensions of the computational domain attained a numerical areal blockage ratio of

152 less than 2% to the external duct diameter to ascertain the absence of far-field effects [44].
153 A domain length of $9D$ was implemented, where the inlet and outlet planes were situated
154 at a distance $3D$ upstream and $6D$ downstream of the duct, respectively, as illustrated in
155 Figure 4. The dimensions of the domain were therefore equivalent to 105 m by 105 m by
156 135 m. The domain surrounding the turbine rotor was segregated from the global domain
157 to induce a moving mesh model with rotation at the turbine rotor relative to a stationary
158 outer domain, with interfaces between the two domains. The no-slip wall condition was
159 implemented on the duct & rotor surfaces. Periodic conditions were allocated to the domain
160 boundaries parallel to the turbine axis. Velocity inlet and pressure outlet conditions were
161 allocated to the perpendicular boundaries. The velocity yaw angle (γ) was induced by
162 varying the incident velocity components at the inlet boundary.

163 In addition, two pairs of planar numerical surfaces were introduced equidistant on either
164 side of the rotor. The primary surface was a circular plane of diameter D_{rtr} . The secondary
165 surface was an annular plane of inner and outer diameters D_{hub} and D_{rtr} , respectively.
166 The prior represented the cross-section of the duct throat, whereas the latter represented
167 the rotor profile with an open-centre. Both planes were introduced within the numerical
168 model at a distance $0.125D_{rtr}$ fore and aft of the rotor, as illustrated in Figure 2b. These
169 numerical surfaces were utilised for data acquisition purposes to attain area-averaged values
170 of normalised axial velocity and static pressure within the turbine duct throat.

171 The Standard Reynolds Stress Model (RSM) ‘Stress-Omega’ (τ - ω) turbulence model was
172 utilised with the SIMPLE pressure-velocity coupling scheme setting, the Green-Gauss node-
173 based gradient, pressure staggering option (PRESTO) pressure, second order upwind mo-
174 mentum, second order upwind specific dissipation rate, and second order upwind Reynolds
175 stresses spatial discretisation settings, and the bounded second order implicit transient for-
176 mulation setting were utilised as the solution methodologies. The Reynolds–Stress Model
177 was preferred to close the Navier-Stokes equation as the Reynolds stresses are solved in three-
178 dimensional space due to the non-implementation of the Boussinesq assumption, prompting
179 superiority in analysing anisotropic flows, such as flows over curved surfaces, flows in rotat-
180 ing fluids, and flows in ducts with secondary (rotational) motion [45]. In addition, the effects
181 of streamline curvature, swirl, rotation, and rapid changes in strain rate are considered in a
182 more effective manner than one-equation or two-equation models. The time-step considered
183 was designated in relation to the tip-speed ratio of the rotor, where each transient iteration
184 was temporally equivalent to one-half of a degree of a turbine revolution, therefore attained
185 by:

$$\Delta t_{step} = \frac{\pi}{360 \cdot \Omega_{sys}} \quad (1)$$

186 where Δt_{step} is the time-step and Ω_{sys} is the turbine rotational velocity. The described
187 numerical setup had been validated in previous works. The validation procedure consisted
188 of a numerical-experimentation comparison of a small-scale tidal turbine. Details in relation
189 to the setup of the numerical validation model may be attained in Ref. [34].

190 A tetrahedral mesh was imprinted upon the turbine domain geometrical model. A mesh
191 independence procedure, described in Table 1, was carried out on the ducted turbine by
192 considering the parameter with the highest degree of dynamics. The mesh independent

193 parameters for the fluid-structure interaction were established utilising ITTC recommended
194 meshing procedures and guidelines [46]:

$$\varepsilon_n = S_n - S_{n-1} \quad (2)$$

$$\Psi = \frac{\varepsilon_n}{\varepsilon_{n-1}} \quad (3)$$

196 where Ψ is the convergence ratio, ε is the difference between the considered variable (S) at
197 different mesh independence study iterations, and the subscript n is the mesh independence
198 study iteration. The turbine torque coefficient (C_Q) was utilised as the mesh independence
199 considered variable (S).

Table 1: Mesh independence analysis for the ducted, high-solidity tidal turbine

n	Cell Number	Cell Number Ratio	S	ε	Ψ
3	18,621,356	1.440	0.1121	-0.00890	0.4113
2	12,932,325	1.270	0.1032	-0.02164	
1	10,185,673		0.08156		

200 Subsequent to the procedure, the final average surface mesh count utilised was marginally
201 above 94,000 cell faces per blade, illustrated in Figure 4b, with more than 18.5 million vol-
202 umetric cells within the entire domain, over 10 million of which within the turbine rotating
203 region. The mesh was implemented with a prism layer at non-slip surfaces with an appro-
204 priate cell height to achieve a y-plus value of $60 \leq y^+ \leq 400$ across the blades and duct.
205 This range was considered due to the high Reynolds number ($> 10^6$) of the system, hence
206 modelling the viscous sublayer was abdicated to reduce computation time.

207 The CFD computations were performed using the ARCHIE-WeSt cluster facility at the
208 University of Strathclyde by running two Intel Xeon Gold 6138 2.00 GHz computational
209 nodes, with 40 cores and up to 192 GB of RAM per simulation. A ducted turbine simulation
210 was completed within ≈ 110.5 wall-clock hours, equivalent to $\approx 4,420$ core-hours, hence
211 resulting in an average of ≈ 5.5 wall-clock hours per turbine rotation.

212 3. Numerical Characterisation

213 3.1. Physical Modelling

214 In consideration of the analysis of a physical turbine, notable definitions concerning
215 the resultant performance outcomes, in terms of the boundary conditions employed, are
216 identified.

217 Utilised to attain open-ocean conditions, the blockage ratio (α_{bl}) is defined as a correla-
218 tion between the device reference area (A_{dvc}) and the domain sectional area (A_{dmn}):

$$\alpha_{bl} = \frac{A_{dvc}}{A_{dmn}} = \frac{\pi R_{dvc}^2}{L_{dmn}^2} \quad (4)$$

219 where R_{dvc} is the device radius, and L_{dmn} is the length of the quadratic cross-sectional area
220 of the computational domain.

221 The tip-speed ratio (TSR) is established as a correlation between the linear blade-tip
222 velocity and the free-stream velocity:

$$TSR = \frac{|\Omega_{sys}|R_{rtr}}{U_\infty} = \frac{|\Omega_z|R_{rtr}}{U_\infty} \quad (5)$$

223 where Ω_{sys} is the system rotational speed, hence Ω_z is the axial angular velocity, U_∞ is the
224 free-stream velocity, and R_{rtr} is the rotor radius.

225 To determine the turbine capacity in converting the fluid free-stream energy into rota-
226 tional energy, the power coefficient (C_P) was established. This considered the mechanical
227 rotational power attained by the device (P_{dvc}) as a ratio of the maximum rotational power
228 potentially acquired in the device area (P_∞):

$$C_P = \frac{P_{dvc}}{P_\infty} = \frac{M_z\Omega_z}{\frac{1}{2}\rho A_{dvc}U_\infty^3} = \frac{M_z\Omega_z}{\frac{1}{2}\rho\pi R_{dvc}^2 U_\infty^3} \quad (6)$$

229 where R_{dvc} is the device radius, M_z is the rotor torque.

230 In relation to the power generated, the torque coefficient (C_Q) evaluated the mechanical
231 torque attained by the device (Q_{dvc}) as a ratio of the maximum torque potentially acquired
232 in the device area (Q_∞):

$$C_Q = \frac{Q_{dvc}}{Q_\infty} = \frac{M_z}{\frac{1}{2}\rho A_{dvc}R_{rtr}U_\infty^2} = \frac{M_z}{\frac{1}{2}\rho\pi R_{dvc}^2 R_{rtr}U_\infty^2} \quad (7)$$

233 In continuation, the resultant thrust on the device induced in a direction parallel to the
234 turbine axis contributed to the fluid-structure phenomenon. The thrust coefficient (C_T) was
235 quantified as a function of the device thrust (T_{dvc}) and the maximum thrust potentially
236 induced upon the device area (T_∞):
237

$$C_T = \frac{T_{dvc}}{T_\infty} = \frac{F_z}{\frac{1}{2}\rho A_{dvc}U_\infty^2} = \frac{F_z}{\frac{1}{2}\rho\pi R_{dvc}^2 U_\infty^2} \quad (8)$$

238 where F_z is the axial force induced upon the turbine.

239 In addition, as a flow bearing was introduced, the resultant force induced in a direction
240 perpendicular to the turbine axis was present. The sway-force coefficient ($C_{F,x}$) was estab-
241 lished as a function of the sway force induced perpendicular to the turbine axis (F_x), and
242 the maximum force potentially induced (F_∞) upon the lateral area of the turbine:

$$C_{F,x} = \frac{F_x}{F_\infty} = \frac{F_x}{\frac{1}{2}\rho A_{dct}U_\infty^2} = \frac{F_x}{\frac{1}{2}\rho L_{dct}D_{dct}U_\infty^2} \quad (9)$$

243

244 To establish the flux through the rotor, the volumetric flow-rate coefficient ($C_{\dot{V}}$) evalu-
245 ated the volumetric flow-rate of the fluid through the rotor (\dot{V}_{rtr}) as a ratio of the maximum
246 volumetric flow-rate potentially attained within the duct:

$$C_{\dot{V}} = \frac{\dot{V}_{rtr}}{\rho A_{rtr} U_{\infty}} = \frac{\dot{V}_{rtr}}{\rho \pi R_{rtr}^2 U_{\infty}} = \frac{\rho \pi R_{rtr}^2 U_{res}}{\rho \pi R_{rtr}^2 U_{\infty}} = \frac{U_{res}}{U_{\infty}} \quad (10)$$

247 where U_{res} is the resultant velocity.

248 Furthermore, the induced axial velocity through the duct (U_z) was compared to the free-
249 stream to attain a quantitative measure of the capacity of flow alignment to the turbine axis
250 by means of an axial velocity coefficient ($C_{U,z}$):

$$C_{U,z} = \frac{U_z}{|U_{\infty}|} \quad (11)$$

251 Identically, the static pressure (P_s) was compared to the dynamic pressure of the free-
252 stream to attain a static pressure coefficient ($C_{P,s}$):
253

$$C_{P,s} = \frac{P_s}{\frac{1}{2} \rho U_{\infty}^2} \quad (12)$$

254 Instituting linear momentum theory, the annular data-extraction planes were utilised to
255 establish the coefficient of disc-thrust (C_{TAD}) by acknowledging the difference between the
256 pressure upstream (P_{s-up}) and pressure downstream (P_{s-dwn}) of the rotor:

$$C_{TAD} = \frac{P_{s-up} - P_{s-dwn}}{\frac{1}{2} \rho U_{\infty}^2} \cdot \frac{A_{disc}}{A_{dvc}} = \Delta C_{P,s} \cdot \frac{A_{disc}}{A_{dvc}} \quad (13)$$

257 where A_{disc} is the planar disc area.

258 3.2. Computational Modelling

259 3.2.1. Conservation Modelling

260 The conservation of mass and momentum formulae were implemented within the CFD
261 model in solving the flow domain:

$$\frac{\partial U_i}{\partial x_i} = 0 \quad (14)$$

$$\rho \frac{\partial U_i}{\partial t} + \rho U_j \frac{\partial U_i}{\partial x_j} = -\frac{\partial P_s}{\partial x_i} + \frac{\partial}{\partial x_j} \left(\mu \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right) - \rho \overline{u'_j u'_i} \right) \quad (15)$$

263 where U_i is the Reynolds-averaged velocity, x_i is the Cartesian coordinate, t is the elapsed
264 time, P_s is the fluid static pressure, μ is the fluid dynamic viscosity, and $-\rho \overline{u'_j u'_i} = \rho \tau_{ij}$ is
265 the Reynolds-stress tensor.

Figure 5: Power coefficient (C_P) in relation to tip-speed ratio (TSR) in validation of the CFD model [34]

266 3.2.2. Turbulence Modelling

267 To close the momentum conservation equation, the $(\tau-\omega)$ turbulence model was imple-
268 mented:

$$\rho \frac{\partial \tau_{ij}}{\partial t} + \rho U_k \frac{\partial \tau_{ij}}{\partial x_k} = \frac{\partial}{\partial x_k} \left[\left(\mu + \frac{\mu_T}{\sigma_k} \right) \frac{\partial \tau_{ij}}{\partial x_k} \right] - \rho P_{ij} - \rho \Pi_{ij} + \frac{2}{3} \beta^* \rho \omega k \delta_{ij} - 2 \rho \omega_k (\tau_{jm} \epsilon_{ikm} + \tau_{im} \epsilon_{jkm}) \quad (16)$$

$$\rho \frac{\partial \omega}{\partial t} + \rho U_j \frac{\partial \omega}{\partial x_j} = \frac{\partial}{\partial x_j} \left[\left(\mu + \frac{\mu_T}{\sigma_k} \right) \frac{\partial \omega}{\partial x_j} \right] + \alpha \frac{\rho \omega}{k} \tau_{ij} \frac{\partial U_i}{\partial x_j} - \beta_o f_\beta \rho \omega^2 \quad (17)$$

270 where τ_{ij} is the specific Reynolds-stress tensor, k is the turbulence kinetic energy, ω is the
271 specific dissipation rate, Π_{ij} is the pressure-strain correlation tensor, μ_T is the eddy viscosity,
272 ω_k is the rotation vector, ϵ_{ijk} is the Levi-Civita pseudotensor, f_β is the mean rotation tensor
273 factor, and α , σ_k , β_o , and β^* are closure coefficients.

274 4. Numerical Model Validation

275 Validation of the CFD model was attained in Borg et al. [34], where the power, torque,
276 and thrust coefficients of a numerical tidal turbine were compared to experimentation per-
277 formed by Mycek et al. [40] and high-speed windmill data by Betz [36]. The CFD model
278 attained a coefficient of determination (R^2) of 0.955, 0.889, and 0.946 with the experimen-
279 tation data points along the curves, respectively. Additionally, the numerical wake velocity
280 profiles at distinct locations along the turbine wake were compared to the experimentation

Figure 6: Torque coefficient (C_Q) in relation to tip-speed ratio (TSR) in validation of the CFD model [34]

283 5. Performance of the Ducted High-Solidity Tidal Turbine in Yawed Flow

284 5.1. Power & Torque Coefficients

285 Prior investigations [34] of the ducted, high-solidity tidal turbine in aligned flow ($\gamma = 0^\circ$)
 286 had described a quasi-linear torque coefficient curve attaining a peak value of 0.292 at a TSR
 287 of 1.00, decreasing to 0.115 at a TSR of 2.50. Within yawed flow conditions, variations in
 288 the outcomes were evident along the TSR range, as illustrated in Figure 9. The quasi-linear
 289 correlation was sustained at the distinct bearings, yet the resultant torque increased at yaw
 290 angles of $15^\circ - 30^\circ$ and decreased at 45° . On average, the induced torque varied by 2.52%,
 291 4.52%, 2.35%, and -3.50% at bearings of 15° , 23.2° , 30° , and 45° , respectively. The statistical
 292 deviation of the torque data is illustrated in Figure B.27.

293 The augmentation in torque occurred due to the induced flow within the bi-directional
 294 duct in yawed flow conditions. Prior investigations [33] had numerically investigated the
 295 swallowing capacity of the vacant duct at identical bearings. The normalised axial velocity
 296 varied in relation to yaw bearing. The swallowing capacity of the duct was found to increase
 297 within a bearing range of $15^\circ - 30^\circ$ from aligned flow, with a decrease at a bearing of 45° .
 298 This outcome transpired as a result of the variant static pressure within the duct throat. As
 299 linear momentum theory states that the torque generated by a rotor is proportional to the
 300 flow velocity through the rotor, the elaborated torque augmentation was therefore induced
 301 by the resultant flow acceleration through the duct.

302 In continuation, the power coefficient curve of the ducted, high-solidity tidal turbine in
 303 aligned flows ($\gamma = 0^\circ$) described a short spanning power coefficient curve attaining a peak

Figure 9: Evaluation of the mean ducted turbine torque coefficient (C_Q) at distinct flow bearings in relation to TSR

304 power coefficient of 0.338 at a nominal TSR of 1.75 within a range of 1.00 – 2.50. Within
 305 yawed flow conditions, the resultant power coefficient varied in relation to the induced torque.
 306 Illustrated in Figure 10, a notable outcome was the increase in peak power coefficient at the
 307 distinct bearings, surpassing that at aligned flow. Maximum increases of 1.90%, 3.86%, and
 308 1.90% to values of 0.344, 0.350, and 0.344, at bearings of 15.0° , 23.2° , and 30.0° , respectively,
 309 were defined. Diminished power was acknowledged at $\gamma = 45.0^\circ$; the decrease in power
 310 transpired as a result of a re-circulation zone generated upstream of the rotor. Further
 311 elaborated in Borg et al. [33] and Section 5.6 within this work, the re-circulation zone was
 312 induced due to the duct angle-of-attack with the free-stream. At the angle-of-attack, the
 313 low-pressure zone reduced the static pressure on the rotor upstream blade area, resulting in
 314 lower power & torque generated. As a result, the 23.2° bearing was established to be the
 315 highest power generating condition.

316 Due to the augmentation in power coefficient, the variation in true power at the distinct
 317 yaw bearings was investigated, illustrated in Figure 11. From a null bearing, as the flow
 318 angle increased to 15° , the power coefficient variation was the most substantial at higher
 319 TSRs (2.00 – 2.50). The 23.2° bearing attained the highest performance values, establishing
 320 a power augmentation along the entire TSR range, with a peak mechanical power value of
 321 1.975 MW. Subsequent bearings pertained diminishing performance values.

322 Further to the mean power generated, the transient output of the rotor was considered.
 323 The variation in power output with azimuth angle (ϕ_r) at the nominal tip-speed ratio of each
 324 free-stream bearing was investigated within five rotational cycles, as illustrated in Figure 12.
 325 When succumb to aligned flow, a variance in mechanical power was recognised due to flow
 326 fluctuations [34] as a result of vortex ring shedding. Within a bearing range of $15^\circ - 30^\circ$, a
 327 diminishment in fluctuation was observed, signifying a reduction in vortex shedding effects.

Figure 10: Evaluation of the mean ducted turbine power coefficient (C_P) at distinct flow bearings in relation to TSR

328 At a bearing of 45° , synchronised outcome fluctuations were evident, with eight fluctuations
 329 per cycle, equivalent to the rotor blade number. The fluctuations were acknowledged to be
 330 due to the low pressure induced by the re-circulation zone.

331 Due to the fluctuations within a rotation cycle, the mean response of a rotor blade during
 332 its rotation, illustrated in Figure 13, was analysed. The outcome throughout the rotation
 333 was attained by synchronising the output of each of the eight blades along five cycles by
 334 azimuth angle, and subsequently averaging the output per blade per cycle at each azimuth
 335 angle. A cycle-averaged disc output was thereby attained. The output was multiplied by
 336 the blade number for comparison purposes.

337 At aligned flow ($\gamma = 0^\circ$), the mean performance was consistent along the turbine rotation.
 338 Upon the introduction in flow bearing ($\gamma = 15^\circ, 23.2^\circ, 30^\circ$), the free-stream velocity induced
 339 perpendicular and parallel vector components to the rotor plane. Due to the local flow
 340 acceleration along the cross-sectional plane parallel to the rotor axis [33], the angle-of-attack
 341 augmented, skewing the resultant performance.

342 In a cylindrical coordinate system, at $\phi_r = 90^\circ$ and $\phi_r = 270^\circ$, the rotational velocity
 343 vector of the rotor blade foil acted along the tangential axis, whereas the free-stream vector
 344 components acted along the axial and radial axes. Therefore, as the local flow accelerated, a
 345 variation in the angle-of-attack along the blade was induced, resulting in a power generation
 346 increase in comparison to that within aligned flow.

347 At azimuth positions $\phi_r = 0^\circ$ and $\phi_r = 180^\circ$, the rotational velocity vector of the rotor
 348 blade foil acted along the tangential axis, with the free-stream vector components acting
 349 along the axial and tangential axes. As the rotational velocity vector was present in opposite
 350 directions on a two-dimensional plane at the two positions, the interaction of the tangential
 351 vectors diminished and enhanced the angle-of-attack, at $\phi_r = 0^\circ$ and $\phi_r = 180^\circ$ respectively,

Figure 11: Evaluation of the true mean power at nominal TSR in relation to flow bearing (γ)

352 resulting in the variation in power generation. The free-stream bearing of $\gamma = 45^\circ$ brought
 353 about a notable outcome, with a significant dip in efficiency at $\phi_r = 90^\circ$.

354 5.2. Thrust Coefficient

355 In recognition of the torque enhancement within a distinct flow bearing range, it was
 356 evident that the loading upon the blades had increased. To ascertain this aspect, the thrust
 357 coefficient of the system, together with duct and rotor discretisation, was investigated.

358 Within aligned flows, the turbine system curve portrayed a peak value of 1.08 at low
 359 TSR, which decreased in a polynomial manner to 0.77 at high TSR. When succumb to yawed
 360 flows, a coefficient increase was acknowledged at bearings of 15° and 23.2° , distinctively at
 361 higher TSRs, as illustrated in Figure 14. The highest values of thrust throughout the TSR
 362 range were attained at the 23.2° bearing, with a thrust coefficient of 1.10 at low TSR,
 363 decreasing to 0.91 at high TSR. The rotor was succumb to $\approx 69\%$ of the total axial load.
 364 The system thrust diminished at 30° and 45° flow bearing. The statistical deviation of the
 365 thrust data is detailed in Figure B.28.

366 Solely acknowledging the rotor thrust, the variation with TSR resembled that of the
 367 torque coefficient, which defined a quasi-equivalent outcome as $\gamma = 0^\circ$ at $\gamma = 15^\circ, 30^\circ$ with
 368 an increase at higher TSRs. An enhancement in thrust was established at $\gamma = 23.2^\circ$, with
 369 a diminishment at $\gamma = 45^\circ$. Due to the increase in thrust and torque at higher TSRs, it
 370 was therefore evident that a higher degree of axial force loading was induced within the flow
 371 parameters.

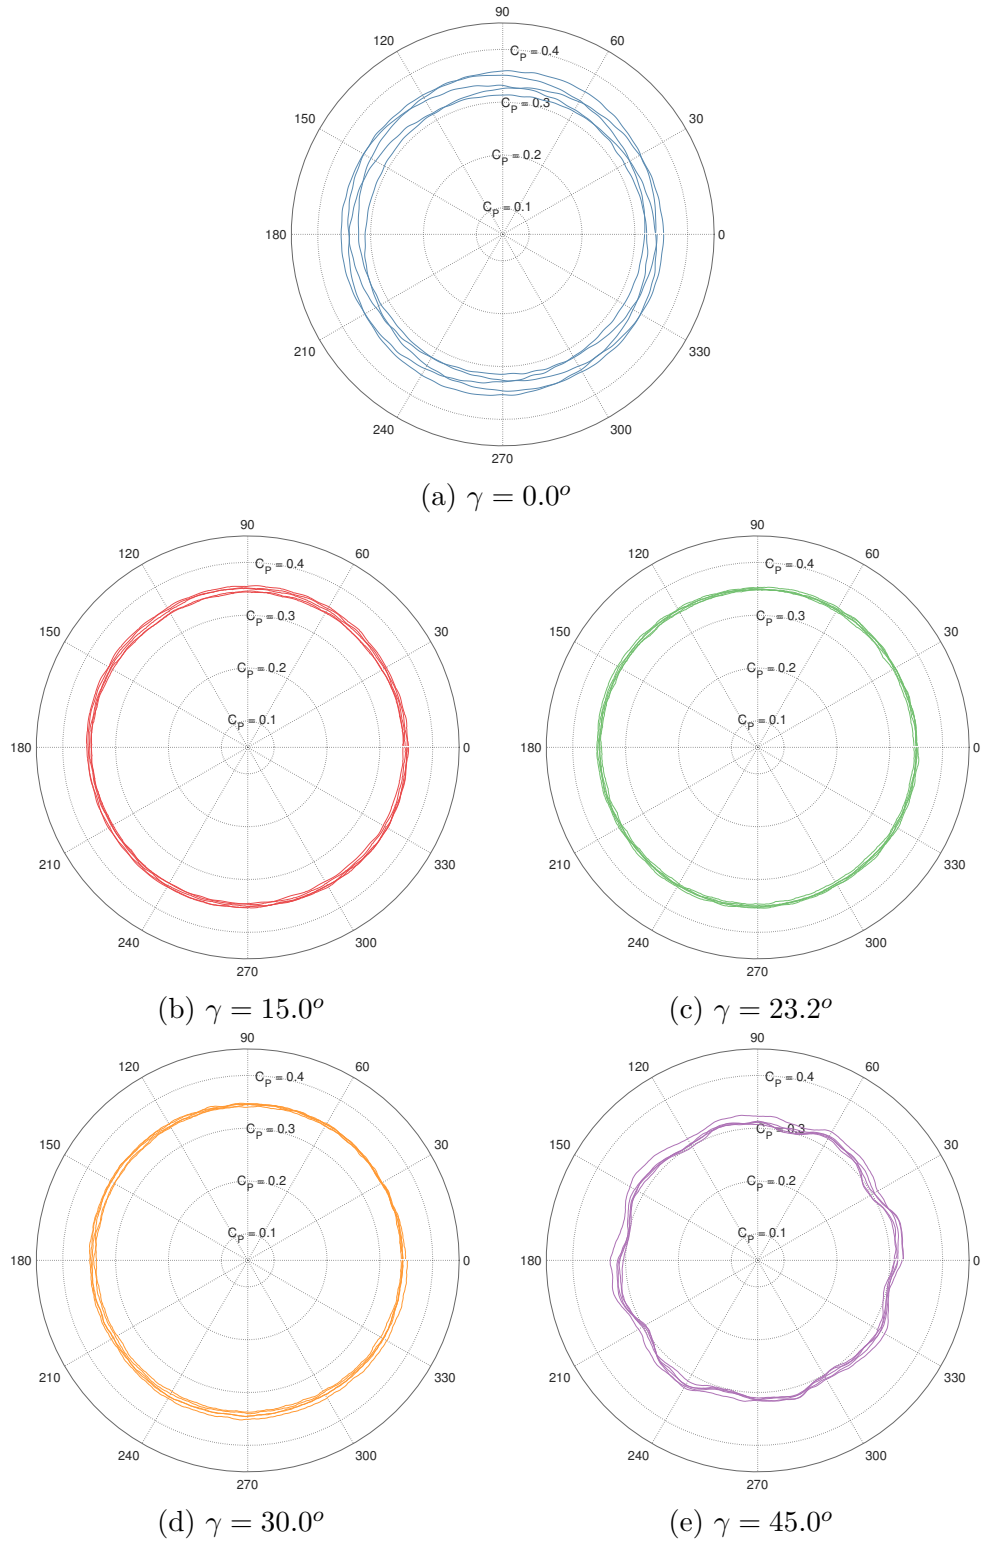

Figure 12: Instantaneous ducted turbine power coefficient (C_P) along rotary operation in relation to blade azimuth angle (ϕ_r) at nominal TSR

Figure 13: Evaluation of the mean single-blade response (C_P) in relation to azimuth angle (ϕ_r) at a TSR of 1.75

372 *5.3. Linear Momentum Analysis*

373 *5.3.1. Axial Velocity Coefficient & Volumetric Flow Rate Coefficient*

374 Utilising the data-acquisition planar surfaces introduced fore and aft of the rotor, the
 375 area-averaged axial velocity was analysed as equivalence at both planes was acknowledged.
 376 Illustrated in Figure 15, the axial velocity through the duct was consistent along the yaw
 377 bearing range, specifically at high TSR values, acting in proportion to the turbine rotational
 378 velocity. The highest axial flow values were attained at the nominal bearing of $\gamma = 23.2^\circ$.
 379 Within the analysis, a maximum coefficient of 0.84 was achieved at high TSR . This outcome
 380 portrayed the capacity of the shroud installation in sustaining axial velocity through a rotor
 381 when succumb to yawed free-stream velocities.

382 Furthermore, the volumetric flow rate was detailed, illustrated in Figure A.26. This was
 383 established to acknowledge the true flow through the duct, as the axial velocity through the
 384 duct solely represented the axial component of the resultant flow vector, moreover at high
 385 free-stream bearings. The axial velocity coefficient was $\approx 98\%$ of the volumetric flow rate
 386 coefficient.

387 *5.3.2. Static Pressure Coefficient*

388 Analysing the pressure drop fore to aft of the rotor, illustrated in Figure 16, a quasi-
 389 linear trend was apparent throughout the bearing range. Identical to the thrust and torque
 390 variations, the pressure difference at yaw bearings of $\gamma = 15^\circ, 23.2^\circ, 30^\circ$ were similar to that
 391 at aligned flows, with increased values at higher TSR s. The largest pressure difference along
 392 the curve was attained at the nominal bearing of $\gamma = 23.2^\circ$. A diminishment in pressure

Figure 14: Evaluation of the mean ducted turbine thrust coefficient (C_T) at distinct flow bearings in relation to TSR

393 difference was attained at a yaw angle of $\gamma = 45^\circ$. The increase in static pressure difference
 394 at distinct bearings therefore elucidated the increased loading, and identified the causation
 395 in the enhanced torque and thrust.

396 Discretising the variation in static pressure difference by flow bearing, illustrated in
 397 Figure 17, the pressure difference values increased with a variation in bearing from aligned
 398 flow at $\gamma = 0^\circ$ to nominal bearing at $\gamma = 23.2^\circ$, attaining the highest values of pressure
 399 difference at the TSR range. The pressure difference then decreased at post-nominal angles
 400 ($\gamma > 23.2^\circ$).

401 In an effort to establish the variation in pressure difference, the pressure upstream and
 402 downstream of the rotor were analysed in segregation, illustrated in Figures 18 and 19
 403 respectively. The pressure induced upstream of the rotor diminished in relation to an increase
 404 in yaw angle as the exposed frontal area of the duct inlet plane decreased. Ref. [33] analysed
 405 the variation in static pressure within the vacant duct, elaborating its decrease until the
 406 occurrence of flow separation. This response similarly transpired within the current analysis,
 407 yet flow separation without reattachment did not occur due to the presence of the rotor.

408 The downstream pressure, at the outlet of the duct, was more unique in response. When
 409 succumb to aligned flow, the static pressure increased in a polynomial manner in proportion
 410 to rotational velocity. Within yawed flow, the static pressure varied distinctively along
 411 the flow bearing range. At lower TSRs, the static pressure at all bearings increased with

Figure 15: Evaluation of the mean axial velocity coefficient ($C_{U,z}$) at distinct flow bearings in relation to TSR

412 an enhancement in rotational velocity. Yet, towards higher TSRs, a diminishing trend in
413 downstream pressure was acknowledged solely for non-aligned yaw bearings. The trend
414 variation established the causation of the enhancement in static pressure drop.

415 Physically, within aligned flow, the wake exited the duct in a direction normal to the
416 rotor plane, inducing back pressure at the duct outlet. Upon yawed flow, the free-stream
417 interacted with the wake, shifting its orientation towards the flow bearing. As a result of the
418 wake shift, the back pressure at the duct outlet diminished, thereby decreasing the static
419 pressure downstream of the rotor.

420 5.3.3. Linear Momentum Thrust Coefficient

421 To verify the established results, linear momentum theory was implemented to determine
422 the static pressure difference through the rotor in relation to the thrust upon the blades. Ap-
423 plying Equation 13, the disc thrust coefficient (C_{TAD}) was compared to the blade-integrated
424 thrust coefficient (C_T), as illustrated in Figure 20, attaining good comparison. The actuator
425 disc outcomes were found to underestimate the result. Utilising the coefficient of deter-
426 mination (R^2), the relation between the two methodologies was 0.942, 0.915, 0.901, 0.862,
427 and -0.770 for the bearings 0.0° , 15.0° , 23.2° , 30.0° , and 45.0° , respectively. The coefficient
428 of determination decreased proportional to the bearing angle, and negating at the high-
429 est bearing. This was due to the inapplicability of an area-averaged assumption at large
430 yaw bearings as dynamic property inconsistencies, such as regions of flow separation, were
431 brought about along the rotor area.

Figure 16: Evaluation of the mean static pressure difference coefficient ($\Delta C_{P,s}$) at distinct flow bearings in relation to TSR

432 5.4. Lateral Load Coefficient

433 The lateral force, acting perpendicular to the rotor axis, upon the turbine was estab-
434 lished as a result of the free-stream bearing variation. Illustrated in Figure 21, the induced
435 force enhanced proportionally to yaw bearing as the free-stream velocity vector component
436 perpendicular to the turbine axis increased. Within aligned flows, minute lateral forces were
437 generated upon the structure. At nominal bearing ($\gamma = 23.2^\circ$), a mean force coefficient of
438 0.411 was acknowledged. The resultant force was largely instigated upon the duct ($\approx 98\%$),
439 with a minute degree of the resultant force acting upon the rotor.

440 5.5. Duct Static Pressure Coefficient

441 In analysis of a vacant duct [33], the variation in flow bearing shifted the angle-of-attack
442 with the geometrical profile of the duct inlet. The stall limit was reached, inducing flow
443 separation along the inner duct surface. To similarly acknowledge the effects of a yawed
444 flow-stream upon the ducted turbine inlet, a static pressure distribution along the upstream
445 section of the duct was established, depicted in Figure 22. The surfaces were discretised by
446 their internal and external positions, in starboard and port directions.

447 Within aligned flows [34], pressure was sustained along the internal duct surface, whereas
448 suction was dominant throughout the external duct surface. The pressure stagnation zone
449 was present as a circular ring along the internal duct surface.

450 With an increase in yaw bearing, the pressure stagnation ring skewed. At $\gamma = 15^\circ, 23.2^\circ$,
451 the stagnation ring was sustained along the internal duct surface. At starboard, the stag-
452 nation point shifted into the duct, closer to the rotor. At port, the stagnation point shifted
453 away from the rotor, with that at $\gamma = 23.2^\circ$ present at the inlet leading edge.

Figure 17: Evaluation of the mean static pressure difference coefficient ($\Delta C_{P,s}$) at distinct TSRs in relation to flow bearing (γ)

454 At $\gamma = 30^\circ, 45^\circ$, the stagnation ring overlapped upon the internal and external duct
455 surfaces. The stagnation point at starboard was retained upon the internal duct surface,
456 shifting further into the duct, whereas the stagnation point at port was present upon the
457 external duct surface. Figure 23 puts forward a qualitative illustration of the upstream
458 stream-tube boundaries, acknowledging the points of stagnation.

459 Along the internal surfaces, pressure was predominantly sustained at starboard. At
460 port, a diminishment in pressure was acknowledged relative to yaw angle, with suction
461 being dominant at $\gamma = 30^\circ, 45^\circ$. Along the external surfaces, pressure was sustained at port,
462 whereas suction was dominant at starboard.

463 5.6. Wake Profiles

464 In visualising the velocity flow contours of the domain, the wake varied in orientation
465 to the flow bearing, as illustrated in Figure 24. As a result of the shift, vortical flow
466 was generated along the duct structure, portraying blunt body properties. Distinctively
467 focusing upon the port side of the turbine, the generation of flow separation in relation
468 to yaw bearing is illustrated in Figure 25. At $\gamma = 0^\circ$, flow was consistent within the
469 duct. At $\gamma = 23.2^\circ$, slight flow separation occurred, which recovered upstream of the rotor.
470 At $\gamma = 45^\circ$, significant flow separation was present upstream of the rotor. At the flow
471 bearing, the separated flow did not recover, resulting in a re-circulation zone to be developed
472 immediately upstream of the rotor, establishing a region of low pressure interacting with
473 the blades at port. The production of a re-circulation zone at a distinct angle-of-attack had
474 been acknowledged by Borg et al. [33] due to the low-pressure zone induced within the duct,
475 occurring as the yaw bearing approached and exceeded the stall angle of the duct inlet,

Figure 18: Evaluation of the mean static pressure coefficient ($C_{P,s}$) upstream at distinct flow bearings in relation to TSR

476 resulting in the production of flow separation. The flow structure induced the dip in torque
 477 at an azimuth angle of 90° .

478 6. Conclusion

479 This study put forward an investigation into the hydrodynamic performance of a ducted,
 480 high-solidity tidal turbine in yawed flow conditions utilising blade-resolved, unsteady com-
 481 putational fluid dynamics, coupled with the τ - ω Reynolds-Stress Model turbulence model.
 482 The research strived to overcome the limitations of prior analyses by acknowledging the
 483 explicit physicality of the rotor blades.

484 Through blade-integrated results, the power coefficient was found to increase at higher
 485 rotational velocities within the 15° - 30° yaw angular range. At these conditions, the maxi-
 486 mum power coefficient was found to reach a value of 0.35 at a bearing of 23.2° . In recognition,
 487 the induced thrust was analysed, noting an increase in axial loading within the yaw range
 488 at higher tip-speed ratios.

489 Acknowledging the parametric variation, linear momentum theory was utilised in an
 490 effort to verify the portrayed characteristics. Area-averaged outcomes of axial velocity and
 491 static pressure were extracted from implemented numerical planes created fore and aft of
 492 the rotor within the CFD model. It was established that, due to the presence of the duct,
 493 the axial velocity was sustained through the rotor. Further to this, the pressure difference
 494 across the rotor augmented within the yaw bearing range, peaking at $\gamma = 23.2^\circ$. The increase
 495 was due to the diminishment of static pressure at the outlet of the duct at higher TSRs.
 496 Post-nominal bearings portrayed a decrease in pressure difference due to flow separation
 497 induced upstream of the rotor. Power augmentation was hence restricted by the stall limit

Figure 19: Evaluation of the mean static pressure coefficient ($C_{P,s}$) downstream at distinct flow bearings in relation to TSR

498 of the shroud inlet profile. Albeit the advantageous enhancement and sustainment of the
 499 turbine power coefficient at distinct flow bearings, Borg et al. [35] acknowledged that the
 500 rotor blades may be succumb to substantial vibrational effects, bringing about an increased
 501 possibility of failure by fatigue throughout operation.

502 It was concluded that the duct installation sustained axial velocity along the bearing
 503 range, together with inducing a diminishment in pressure downstream of the rotor, resulting
 504 in an augmented pressure drop. The rotor thrust, in conjunction with torque and power,
 505 was hence enhanced, ensuing in the performance improvement of the ducted turbine.
