Effects of early life stress and subsequent re-exposure to stress on neuronal activity in the lateral habenula

Jack F. Webster[1], Sanne Beerens[1] and Christian Wozny[1,2 ✉]

Early life stress can result in depression in humans and depressive-like behaviour in rodents. In various animal models of depression, the lateral habenula (LHb) has been shown to become hyperactive immediately after early life stress. However, whether these pathological changes persist into adulthood is less well understood. Hence, we utilised the maternal separation (MS) model of depression to study how early life stress alters LHb physiology and depressive behaviour in adult mice. We find that only a weak depressive phenotype persists into adulthood which surprisingly is underpinned by LHb hypoactivity in acute slices, accompanied by alterations in both excitatory and inhibitory signalling. However, while we find the LHb to be less active at rest, we report that the neurons reside in a sensitised state where they are more responsive to re-exposure to stress in adulthood in the form of acute restraint, thus priming them to respond to aversive events with an increase in neuronal activity mediated by changes in glutamatergic transmission. These findings thus suggest that in addition to LHb hyperactivity, hypoactivity likely also promotes an adverse phenotype. Re-exposure to stress results in the reappearance of LHb hyperactivity offering a possible mechanism to explain how depression relapses occur following previous depressive episodes.

INTRODUCTION

The lateral habenula (LHb) is an evolutionarily conserved brain structure located within the epithalamus which encodes aversive events [1, 2], and depressive behaviour [3–6]. Specifically, the LHb becomes hyperactive in depression [3, 4, 7–9], thus enhancing output to the midbrain reward circuitry, for which the LHb acts as an inhibitory modulator [10–12].

Indeed, many studies have employed the use of a variety of different animal models of depressive behaviour including chronic mild stress [13], chronic restraint stress [4, 6], social defeat [14, 15], learned helplessness [3] and various models of early life stress [8, 16–18], and have independently reached this conclusion that the LHb becomes hyperactive in depression. However, the majority of these studies have carried out experimentation shortly after exposure to the relevant stressor, and as such there is comparatively little evidence as to the long-term persistence of depressive phenotype, and the corresponding synaptic and physiological alterations within the LHb [18].

Hence, in this study we aimed to assess how early life stress in the form of maternal separation influences depressive behaviour, and alters lateral habenular physiology and synaptic connectivity in adult mice. Furthermore, we then sought to ask how early life stress influences subsequent re-exposure to stress in adulthood.

MATERIALS AND METHODS

Brief summaries of methods can be found below. Complete materials and methods can be found in the supplementary materials.

Animals

All procedures were approved by the Ethics committee of the University of Strathclyde, Glasgow, and carried out in accordance with the relevant UK legislation (the Animals (Scientific Procedures) Act, 1986). C57BL/6J and SOM-IRES-Cre mutant mice were kept on a 12:12 light/dark cycle under standard group housing conditions with unlimited access to water and normal mouse chow, unless otherwise stated. Both males and females were used in this work, and unless otherwise stated, data were pooled between genders.

Maternal separation procedure

The maternal separation (MS) procedure was adapted from a previously published protocol [8]. Briefly, at postnatal day 6 (P6) litters were separated into groups of either control (CTRL) pups, which remained with the mother, or MS pups, which were separated into individually isolated compartments of a heated cage in a separate room for 6 h per day from P6-16. MS pups were then weaned early at P17.

Behavioural testing and acute restraint procedure

Mice underwent behavioural testing at approximately 8–10 weeks, and were single housed for these experiments. 3 behavioural tests were implemented in this study. These were sucrose preference, the open field test, and the splash test. Mice were then returned to group-housing conditions upon completion of behavioural testing. For animals which underwent acute restraint, this was carried out for a period of 1 h in a modified handling tube.

Stereotaxic viral injections

Stereotaxic viral injections were carried out as previously described [19]. Briefly, SOM-IRES-Cre heterozygous mice were deeply anaesthetized with

[1]Strathclyde Institute for Pharmacy and Biomedical Sciences, University of Strathclyde, Glasgow G4 0RE, UK. [2]MSH Medical School Hamburg, Medical University, Institute for Molecular Medicine, 20457 Hamburg, Germany. ✉email: christian.wozny@medicalschool-hamburg.de

inhaled isoflurane and transferred to a stereotaxic frame where viral injections (either AAV9-EF1a-DIO-hChR2(H134R)-EYFP, titre 1.8×10^{13} vg/mL, 200 nL; or AAV9-pCAG-FLEX-EGFP-WPRE, titre 2.5×10^{13} vg/mL, 100 nL) were performed bilaterally at the following stereotaxic coordinates (from Bregma): AP 0.45; ±1.3; depth 5.8. Following completion of surgery, animals were given at least two weeks to allow expression of the virus before acute slice preparation for electrophysiology.

Acute brain slice preparation and in vitro electrophysiological recordings

Mice were humanely euthanized by cervical dislocation and immediately decapitated. Brains were rapidly removed, brains slices were prepared following standard procedures and electrophysiological recordings were performed as previously described [19, 20].

Transcardial perfusion, immunohistochemistry and confocal microscopy

Mice were terminally anaesthetized by intraperitoneal injection of 50% lidocaine and 50% pentobarbital, and then perfused through the left ventricle with 0.1 M PBS followed by perfusion with 4% PFA dissolved in PBS. Brains were then removed and fixed overnight in 4% PFA in PBS, after which they were cryoprotected in a solution containing 30% sucrose in PBS where they were kept until required for histology. Immunohistochemical staining against c-Fos was then performed as previously described [19], and slices were imaged on a Leica SP8 confocal microscope.

RESULTS
Early life stress induces mild depressive symptoms in adult mice, and alters LHb physiology

We first sought to validate that MS for 6 h per day with early weaning (methods) can induce depressive behaviour in adult mice. Hence, following MS, mice were allowed to develop to adulthood (≈8–10 weeks of age), when they underwent behavioural testing. Mice were subjected to a series of 3 behavioural paradigms to test for anhedonia, anxiety-like behaviour and motivation which were sucrose preference, the open field test and the splash test respectively (Fig. 1A; N = 37 CTRL; N = 39 MS mice). Sucrose preference testing was carried out over 3 consecutive days, and indeed we saw a reduction in sucrose preference in MS mice over these 3 days (Fig. 1B; $p = 0.038$; 2-way ANOVA column factor). However, a particularly striking effect was that this deficit was most prominent on day 2 of testing ($p = 0.028$; Sidak's test). This was an interesting observation, as on day 2 of our paradigm, we switched the position of the sucrose and water bottles (Methods), hence suggesting that our model also induces a possible deficit in reversal learning [21]. We did not observe any change in anxiety-like behaviour (Fig. 1C; $p = 0.670$; unpaired T-test), locomotor activity (Fig. 1D; $p = 0.593$; unpaired T-test) or motivation (Fig. 1E; $p = 0.286$; unpaired T-test). However, MS mice exhibited an increased latency to first grooming bout in the splash test (Fig. 1F; $p = 0.050$; Mann-Whitney test), and interestingly spent more time rearing in the splash test (Fig. 1G; $p = 0.020$; unpaired T-test), which may be indicative of social contact seeking [22]. To account for variability between behavioural tests within individual mice, we also calculated an integrated Z score [23], which gives an arbitrary score of emotionality for each mouse, by normalising and integrating readouts from each behavioural test. This indeed revealed that MS mice had overall greater emotionality than CTRL mice (Fig. 1H; $p = 0.019$; unpaired T-test). However, overall these results led us to conclude that the observed phenotype was relatively mild in the adult mice.

We next sought to assess how MS altered LHb neuronal physiology. Mice were sacrificed shortly after behavioural testing, and whole-cell recordings were carried out in acute brain slices (Fig. 2A; n/N = 36/6 CTRL; n/N = 39/6 MS neurons/mice). MS induced no changes in passive physiological properties (Fig. S1A; input resistance $p = 0.984$; unpaired T-test; and resting membrane potential $p = 0.235$; Mann-Whitney test), and induced only a weak trend towards an increase in intrinsic excitability (Fig. S1B, C; $p = 0.083$; 2-way ANOVA column factor). However, the most striking difference we observed was a reduction in spontaneous neuronal activity (Fig. 2B, C; $p = 0.0009$; Chi-square test), which appeared to be specific for tonically active neurons. This was an interesting observation as bursting activity of LHb neurons is believed to be the primary driver of depressive behaviour [4, 6]. Moreover, of those neurons which were spontaneously active, we observed that they were active at a lower frequency following MS (Fig. 2D; $p = 0.014$; Mann-Whitney test). We did not however observe any correlation between the mean spontaneous activity for each mouse and corresponding behavioural Z score, likely as 3 out of 6 mice which we recorded from had mean spontaneous activity close to 0 (Fig. 2E). We also observed no difference in sag potential between conditions (Fig. 2F, G; $p = 0.678$; 2-way ANOVA column factor). However, although neurons from MS mice did not display more bursting activity at rest, we found that they did fire rebound bursts with a reduced latency following hyperpolarising current injection (Fig. 2H, I; $p < 0.0001$; 2-way ANOVA column factor), leading us to speculate that the neurons may be in a state where they are more primed to fire in response to synaptic input. Hence, we also recorded spontaneous excitatory postsynaptic currents (sEPSC's) in a separate cohort of mice (Fig. S2; n/N = 44/4 CTRL; n/N = 46/4 MS neurons/mice). We did not observe any differences in frequency (Fig. S2A; $p = 0.342$; Mann-Whitney test) but did observe a slight but significant reduction in current amplitude following MS (Fig. S2A; $p = 0.012$; Mann-Whitney test). However, this dataset was likely confounded by the fact that the CTRL mice for this particular cohort appeared to display a phenotype more similar to the MS mice than other CTRL mice, and as such we attempted to account for this by plotting the behavioural Z score of each mouse against the mean sEPSC frequency for all cells recorded from each individual mouse (Fig. S2C). Indeed, when we did this we observed a negative correlation between Z score and mean sEPSC frequency (Fig. S2C; $p = 0.016$; simple linear regression), indicating that mice which existed in a more depressed state apparently exhibited reduced excitatory drive onto LHb neurons. Altogether, these results point to a scenario whereby MS reduces spontaneous firing of LHb neurons in brain slices, possibly by reducing presynaptic excitatory drive.

MS weakens inhibitory synaptic transmission onto LHb neurons

Multiple other works have shown that a reduction in inhibitory signalling is associated with a depressive phenotype [7, 8, 24], and as such we sought to test how MS influenced inhibitory signalling in adult mice. We first recorded spontaneous IPSCs (sIPSCs) throughout the LHb in acute slices (Fig. 3; n/N = 46/6 CTRL; n/N = 49/6 MS neurons/mice). We observed no overall difference in either frequency (Fig. 3A; $p = 0.296$; Mann-Whitney test) or amplitude (Fig. 3A; $p = 0.245$; Mann-Whitney test). However, we did observe a striking gradient across the mediolateral axis of the LHb in CTRL mice (Fig. 3B, C; $p = 0.005$; simple linear regression) with sIPSC frequency being greatest in the medial LHb, which was not present in MS mice (Fig. 3B, C; $p = 0.325$; simple linear regression). This thus lead us to suspect that there may be subregional differences in spontaneous inhibitory synaptic input to LHb neurons. Indeed, when we broke our analysis down into the medial (<0.45 mm from midline) and lateral (>0.45 mm from midline) LHb sub-regions, we observed a reduction in sIPSC frequency specifically in the medial LHb (Fig. 3D; $p = 0.048$; Mann-Whitney test). Furthermore, we found that there was a negative correlation of the behavioural Z score with IPSC frequency (Fig. 3E; $p = 0.013$; simple linear regression), thus suggesting that more depressed animals exhibited lower levels of inhibitory synaptic drive. Overall, these results suggest that MS results in a reduction in spontaneous inhibitory input, specifically in the medial LHb.

In our previous work we reported on a strong inhibitory projection to the LHb which appeared to arise from somatostatin-positive (SOM) neurons in the ventral pallidum of the basal forebrain [19]. Other work has shown that excitatory pallidal projections to the LHb can promote depressive behaviour [15], and that inhibitory LHb-projecting pallidal projections promote reward [25]. As such, we hypothesised that inhibitory drive onto the LHb from SOM-positive pallidal neurons may be lost following MS. We tested this by injecting a Cre-dependent virus encoding channelrhodopsin (ChR2) into the basal forebrain of SOM-Cre mice and recorded light-induced postsynaptic events in LHb neurons (Fig. 4A; $n/N = 18/4$ CTRL; $n/N = 20/4$ MS neurons/mice). At least 2 weeks post-injection, we could observe eYFP-positive terminal fields within the LHb (Fig. 4B). We first recorded inhibitory currents induced following a single 1 ms pulse at various intensities, and tested for differences between CTRL and MS mice by fitting a one-phase association exponential curve to each dataset [26]. CTRL and MS groups were found to have very different curve fits (Fig. 4C; $p < 0.0001$; non-linear curve fit), which specifically was found to be a reduction in the curve plateau for MS mice (Fig. 4C, D; $p = 0.03$; non-linear curve fit), thus suggesting a reduction in postsynaptic current amplitude without a corresponding change in kinetics. We also tested presynaptic release probability in current clamp configuration and observed no differences (Fig. 4E; $p = 0.457$, 2-way ANOVA). However, an interesting observation was that in a sub-fraction of responsive neurons, the inhibitory drive was found to be strong enough to induce rebound firing (Fig. S3A, B), which interestingly was observed to be strongest at 10 Hz stimulation frequency (Fig. S3C).

Altogether, the above observations indicate a weakening of inhibitory synaptic drive from inhibitory SOM-positive pallidal

forebrain neurons onto LHb neurons following MS. Due to the observed change in plateau without corresponding change in rise constant of the curve (Fig. 4C), and the apparent lack of change in presynaptic release probability (Fig. 4E), the case could be made that this may be due to a down-regulation of postsynaptic GABA receptors. However, this does not innately rule out a change in the intrinsic excitability of the presynaptic neurons. As such, we aimed to test this by recording from presynaptic SOM-positive pallidal neurons. We first injected a retrograde Cre-dependent virus encoding tdTomato into the LHb of SOM-Cre mice. However, while we could clearly observe terminals in the LHb, and tdTomato-positive soma in the entopeduncular nucleus, where SOM-positive neurons project to the LHb, labelling in the entire basal forebrain region was very sparse (data not shown). Instead, we therefore injected a Cre-dependent anterograde virus encoding eGFP into the basal forebrain and recorded from putative presynaptic eGFP-positive neurons (Fig. S4A; $n/N = 35/4$ CTRL; $n/N = 34/4$ MS neurons/mice). As with our optogenetic experiments, this resulted in robust terminal labelling within the LHb (Fig. S4B). Neurons were found to be spontaneously active at a similar frequency within both conditions (Fig. S4C; $p = 0.977$; Mann-Whitney test) and had similar resting membrane potentials (Fig. S4D; $p = 0.865$; unpaired T-test). However, neurons from MS mice exhibited a reduction in input resistance (Fig. S4D; $p = 0.031$; unpaired T-test), and a slight but statistically significant reduction in action potential firing following depolarising current injection (Fig. S4E, F; $p = 0.040$; 2-way ANOVA column factor). Additionally, these neurons exhibited a strong reduction in sag potential (Fig. S4H, I; $p < 0.0001$; 2-way ANOVA column factor). Hence, all of these observations point to a reduction in excitability in SOM-positive pallidal neurons in adult mice following MS. Altogether
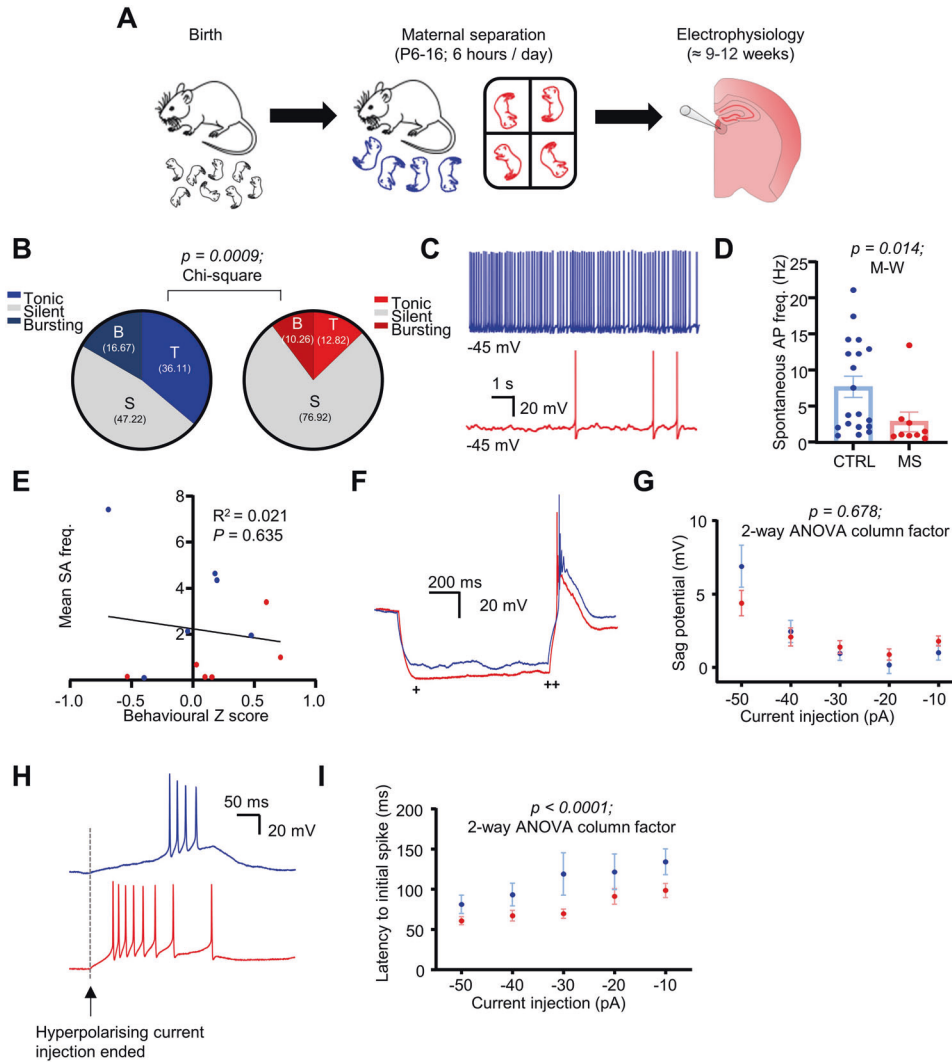

Fig. 2 MS alters LHb neuronal physiology in adult mice. A Schematic illustrating experimental timeline. (**B**–**D**) Spontaneous activity comparison for both conditions. **B** Pie charts depicting percentages of recorded neurons which were classed as spontaneously active (spontaneous AP discharge > 0.5 Hz). **C** Example spontaneous activity recordings from both conditions. **D** Comparison plot of mean spontaneous activity frequency, for neurons which were spontaneously active (>0.5 Hz frequency). **E** XY plot of behavioural z score against mean spontaneous activity frequency calculated for each individual mouse from which electrophysiological recordings were taken. with our optogenetic experiments, these results indicate that MS reduces inhibitory connectivity between the pallidum and forebrain via postsynaptic modifications which may also be accompanied by a presynaptic reduction in neuronal excitability.

MS sensitises LHb neurons to acute stress
Thus far we have shown that MS induces a seemingly mild depressive phenotype within the adult mouse, which is accompanied by reduced activity within the LHb in slices and various synaptic alterations. While the changes we observed in inhibitory transmission (Figs. 3 and 4) appear to fit relatively well with the current literature, our data for the physiological properties of LHb neurons (Fig. 2) apparently goes against the central hypothesis that depression is driven by hyperactivity within the LHb. Referring again to our behavioural data, we speculated that a possible explanation for this may be that rather than being in a strongly depressed state as adults, the mice are in a state where

they are only mildly depressed but rather do not respond particularly well to emotional challenge. Several observations led us to this hypothesis: firstly, the observation that the sucrose preference deficit is strongest on day 2 when the positions of the bottles are switched (Fig. 1B), which may indicate that the MS mice do not respond as well to changes in learned behaviours. Secondly, that the MS mice exhibited an increased latency to groom in the splash test (Fig. 1F). This is a reflection of the fact that the initial reaction of the mice to being sprayed with sucrose solution is to panic and flee, and the MS mice seemingly do this for longer and hence take longer to relax and start grooming. Thirdly, the observation that although not more spontaneously active at rest, the neurons from MS mice fire rebound bursts with a shorter latency (Fig. 2H, I), possibly indicative that they are more primed to fire in response to synaptic drive.

To test this, we therefore submitted both CTRL and MS mice to an acute stressor in the form of 1 hour restraint, then immediately

sacrificed them and performed acute slice recordings (Fig. 5A; $n/N = 56/5$ CTRL; $n/N = 51/5$ MS neurons/mice). As with our previous recordings, we observed no difference in passive physiological properties of LHb neurons (Fig. 5B; input resistance $p = 0.958$; T-test; RMP $p = 0.793$; Mann-Whitney test). However, here we observed a more prominent increase in intrinsic excitability in MS neurons (Fig. 5C; $p < 0.0001$; 2-way ANOVA column factor). Surprisingly, we observed a lesser difference in the latency to rebound burst, although still significant (Fig. 5D; $p = 0.042$; 2-way ANOVA column factor). As hypothesised, we found that a greater fraction of the neurons from MS mice were spontaneously active at rest following acute restraint (Fig. 5E, F; $p < 0.0001$; Chi square test). Moreover, although the average frequency of neurons which were spontaneously active was not found to be different (Fig. 5G; $p = 0.764$; Mann-Whitney test), neurons from the MS mice displayed a differing distribution of spontaneous activity frequencies (Fig. 5H; $p = 0.045$; Kolmogorov-Smirnov test). Interestingly, we also observed a trend towards a positive correlation between the behavioural Z score of the mice and the mean spontaneous activity frequency for each mouse (Fig. 5I; $p = 0.063$; simple linear regression), indicating that the emotional state of the mouse is a reasonably valid predictor of the response of the LHb neurons to stress. We further tested our hypothesis that the LHb neurons are more sensitive to stress histologically, by quantifying expression of the immediate early gene cFos in a separate cohort of both CTRL and MS mice either with or without exposure to acute restraint (Fig. 5J, K; N = 8 CTRL; N = 9 MS; N = 10 CTRL restraint; N = 9 MS restraint mice). Restraint was able to reliably drive cFos expression in both CTRL and MS mice (Fig. 5J, K; $p < 0.0001$; one-way ANOVA), with MS mice exhibiting a trend towards a greater numbers of cFos-positive neurons than CTRL mice following restraint (Fig. 5J; $p = 0.081$; Sidak's test) but not in non-restrained animals (Fig. 5J; $p = 0.718$; Sidak's test), thus further confirming that LHb neurons in MS animals are more sensitised to stress.

Finally, we asked if this increase in activity was synaptically driven. We tested this by recording sEPSC's in slices from CTRL and MS mice following restraint ($n/N = 56/5$ CTRL; $n/N = 55/5$ MS neurons/mice). We observed no difference in sEPSC frequency

(Fig. S5A; $p = 0.950$; Mann-Whitney test) or amplitude (Fig. S5A; $p = 0.974$; Mann-Whitney test), with no obvious correlation to behavioural phenotype (Fig. S5B; $p = 0.223$; simple linear regression). However, we did observe a difference in kinetics, with many neurons in slices from CTRL mice exhibiting distinctive currents with an increased rise time (Fig. S5D; $p = 0.013$; Mann-Whitney test) and a strong trend towards an increased decay (Fig. S5E; $p = 0.051$; Mann-Whitney test) which were less prevalent in MS mice. We also observed a clearly different data distributions for both rise time (Fig. S5D; $p < 0.0001$; Kolmogorov-Smirnov test) and decay (Fig. S5E; $p < 0.0001$; Kolmogorov-Smirnov test). These distinctive currents appeared to be AMPA-mediated in that they were sensitive to the AMPA antagonist NBQX (Figs. S5C and S6; $p < 0.0001$; Dunn's multiple comparisons test), but not the NMDA antagonist AP5 (Fig. S6; $p = 0.324$; Dunn's multiple comparisons test). A possible explanation for this may be differences in AMPA subunit composition between MS and CTRL mice, which reflects differences in ongoing plasticity [27]. Interestingly, AMPA currents with extended kinetics have recently been shown to be involved in the induction of synaptic plasticity in hippocampal principal cells [28], and as such we can speculate that this may be ongoing to a greater extent in CTRL mice, which may be related to the induction of depressive symptoms following restraint stress [6]. Indeed, it would make sense that these events are less prominent in MS mice, where it can be assumed that synaptic potentiation has already occurred to a greater extent. Altogether, these data are indicative of a scenario whereby LHb neurons are more responsive to stress following MS likely via differences in postsynaptic AMPA receptor subunit composition.

DISCUSSION
In this work we have implemented the maternal separation model of depression, in tandem with behavioural assays and in vitro electrophysiological recording techniques to dissect how early life stress influences the behavioural state and the underlying physiology of the LHb in adult mice. We report that the depressive phenotype is relatively weak in the adults. We also find that this is

accompanied by a decrease in spontaneous neuronal activity, with a weakening of synaptic input from inhibitory SOM-positive forebrain neurons. However, rather than being more active at rest, in our model we find that the LHb neurons have a heightened sensitivity to respond to the re-exposure of stressful events. This may offer a neurobiological explanation as to why relapses occur following remission of depressive episodes.

Relating to our conclusions, arguably the most important aspect of our work that must be discussed is the validity of the MS model in successfully inducing depressive symptoms. It is important to note that historically, works implicating the MS model of depression have reported very variable results [29]. Indeed, while some studies have reported that early life stress can reliably induce depressive symptoms and drive LHb hyperactivity [8, 16–18], others have reported a failure of early life stress to induce a depressive phenotype [30, 31], and some evidence has even reported that it can induce resilience in the adult animals [32]. This inherent variability in reliability of MS is likely at least partially explained by inconsistencies in protocols, with longer periods of separation generally being thought to more reliably induce aberrant phenotypes [33]. Furthermore, it has also been shown that variations of the MS protocol in which MS is performed unpredictably (ie. at varying timepoints each day, and not necessarily on consecutive days) are more reliable in inducing depressive symptoms [32, 34]. A further confounding factor is the propensity for MS protocols to induce compensatory maternal care from the dam upon return to the home cage [35, 36], which can alleviate the depressive phenotype. Another possible explanation is species and strain difference: it is believed that mice are generally more resistant to the adverse effects of MS than rats [29, 37], and C57 mice are thought to be particularly resilient [37]. Hence, we employed the maternal separation with early weaning variant of the protocol [38], a variant of the protocol with an extended separation period (6 hours per day) and early weaning at postnatal day 17 to negate the possibility for compensatory care at this critical developmental period which has previously been shown to induce a phenotype in C57 mice, and even with this optimized protocol we could only observe relatively few behavioural deficits. Importantly however, of the behavioural deficits we did observe, these all point in the direction of the MS mice exhibiting a more susceptible phenotype than the CTRL mice, hence ruling out the possibility that our model has also

promoted resilience (Fig. 1). Nonetheless, our findings reinforce the need for more robust MS protocols, which we speculate could possibly be optimized by combining unpredictable MS protocols with early weaning to simultaneously enhance the impact of the MS phase of the protocol while also negating compensatory care pre-weaning.

The next key question that must be addressed is why our model induces a reduction in spontaneous activity within the LHb. It is now very well accepted that LHb hyperactivity promotes depressive behaviour [3, 4, 7–9], and our data does not superficially support this. Firstly, to address this question, we would point to the fact that in healthy animals, the LHb is active to serve an important purpose: that is to encode reward prediction error and prevent reinforcement of behaviours with negative outcomes [39]. Therefore, the relationship between LHb activity level and behavioural phenotype is likely not as simple as heightened activity equalling a more pronounced depressive phenotype, and reduced activity equalling a less depressed phenotype. Hence it may be the case that a reduction in LHb activity is also indicative of an aberrant phenotype. Indeed, a recent hypothesis has proposed that LHb hypoactivity in childhood may promote attention deficit hyperactivity disorder, which in turn primes the LHb to be more responsive to stress in adulthood [40]. Experimental evidence has also shown that LHb inactivation induces a reversal learning deficit [41], which may explain why we see a prominent deficit in sucrose preference when the position of the bottles are switched (Fig. 1B). Thus, LHb hypoactivity is not likely to promote a healthy phenotype. Secondly, and in line with our first point, our recordings in CTRL mice (Fig. 2B) largely agree with the existing literature [4, 17, 18] in the observed distribution of tonic, bursting and silent neurons, thus supporting the claim that background LHb activity is important within healthy animals, and also ruling out the possibility of a recording artefact. Finally, although it is now well accepted that excitatory synaptic drive is potentiated onto the LHb in depression [3], it should also be noted that there is somewhat conflicting evidence in that recent work has also observed a decrease in postsynaptic LHb AMPA receptor expression following exposure to stress [42]. Indeed, our data also suggest that a more depressed phenotype correlates with a reduction in spontaneous excitatory postsynaptic current frequency (Fig. S2B). Accounting for all of this evidence we would

therefore conclude that in addition to LHb hyperactivity, LHb hypoactivity may also promote an aberrant phenotype and as such the reduction in spontaneous activity we observe is not mutually exclusive with the central hypothesis that LHb hyperactivity drives depression.

In terms of inhibitory signalling within the LHb, the literature is relatively consistent in that this promotes behavioural reinforcement [25, 43, 44], and that inhibition of the LHb has an antidepressant effect [45, 46]. Consistent with this, inhibitory signalling has been shown to be perturbed in various models of depression [7, 8, 24], and indeed our data lend further support to

this hypothesis. It is interesting to note that the loss of spontaneous inhibitory input we observed appears to be specific for the medial portion of the LHb (Fig. 3B–D). Previous work has identified a population of inhibitory LHb neurons which resides specifically within the medial LHb [47, 48], and hence one could speculate that activity of this population may be down-regulated following MS, therefore resulting in a loss of local inhibition. Additionally, we also report a reduction in connectivity between inhibitory pallidal neurons and the LHb, which our data also suggest involves a possible presynaptic reduction in excitability (Fig. S4) although we must note that as an anterograde labelling

approach was used here, we cannot say with absolute certainty that these neurons project directly to the LHb. While previous work has characterised inhibitory projections from various pallidal regions to the LHb relatively extensively [14, 25, 43, 49], to our knowledge this is the first time that such a projection has been shown to be implicated in the pathogenesis of a model of depression.

As a final note, here we have focused specifically on early life stress-induced alterations in excitatory and inhibitory signalling within the LHb. However, it should also be noted that there is growing evidence that other neurotransmitters influence LHb activity [50], and conversely that the LHb can influence other transmitter systems downstream. As such it may be the case that alterations in other transmitter systems are driving the physiological changes within our model. Interestingly recent evidence has indicated that early life stress alters Kappa opioid receptor (KOR) signalling at LHb synapses both pre- and postsynaptically, resulting in a loss of LHb excitability in a subset of neurons [17]. Furthermore, KOR signalling was also shown to perturb both GABAergic and glutamatergic drive onto LHb neurons. As we see a loss of both excitatory and inhibitory drive, paired with a reduction in LHb excitability it may be the case that our model is also inducing alterations in KOR signalling within the LHb, thus altering LHb output and control over downstream reward pathways. Assuming this as a possibility, then it is also likely that alterations in other transmitters systems are induced in our model, and further work should serve to elucidate these.

CONCLUSIONS

Depression is a complex disease, with hugely variable aetiology [51]. Our work further complements the existing literature in that we provide evidence that LHb hypoactivity can also be associated with a depressive phenotype, and may be representative of a state where the animal is hypersensitive to stressful events. This work challenges the classical view that within the LHb, hyperactivity is the sole driver state of depressive behaviour. Further work into the specific molecular mechanisms by which these changes occur may shed new light onto the pathogenesis of depression and may unveil novel molecular targets for future therapies.
