Abstract

This paper presents a novel fluorescent receiver for Visible Light Communications that combines a broad field-of-view with a significant gain, and simultaneously enables wavelength-division-multiplexing for data communications. These characteristics are achieved by creating a receiver that includes a stack of two fluorescent optical antennas, each designed to receive a different part of the spectrum and create two separable communication channels. The device outperforms the theoretical étendue limit in terms of the combination of field-of-view and gain it can achieve. Furthermore, the demonstrated de-multiplexing of blue and green spectral components enables the parallel streaming of data by wavelength division

multiplexing. Since these devices are inexpensive, simple and compact, they can easily be integrated into portable electronic devices such as phones, tablets, and laptops.

Introduction

Visible light communication (VLC) is a new paradigm for wireless communications that has the potential to supplement conventional radio-frequency (RF) based wireless communication methods.^[1, 2] Similar to all wireless communication, there is a need for antennas to increase the signal-to-noise ratio (SNR) at the receiver end of the data link to enable or enhance data transfer. In VLC receivers, SNR is typically increased by an optical element, most commonly a lens or a compound parabolic concentrator.^[3, 4] However, the use of these optical elements restricts the field-of-view (FoV), meaning that VLC links are more sensitive to the alignment of the transmitter and the receiver than RF links. This sensitivity is due to a fundamental principle in optics, the conservation of étendue, which creates a trade-off between the gain, and thus the increase in SNR provided by the optical system, and the FoV of the system,^[5] as **Figure 1a** and **b** illustrate. This presents a challenge for implementing a practical VLC link for mobile applications e.g. to a laptop or smartphone, because of the need for constant careful alignment.^[4]

A recent series of publications have demonstrated a novel optical solution to the constraints imposed by étendue using a fluorescent antenna.^[6, 7] It was demonstrated that the gain of the fluorescent optical antenna outperformed by three times the theoretical limit for any refraction-reflection based optical system with the same FoV.^[6] The structure consisted of a fluorescent material sandwiched between two glass layers, as shown in **Figure 1c**. Due to the higher refractive index of the fluorescent layer, part of the fluorescence is trapped by total internal reflection. As a result, this light is guided through the film and escapes at the edges. The relatively large surface area for absorbing the incoming signal, compared with small edge

area of emission leads to an enhancement of the signal's power density, increasing the SNR of the system.

In addition to their other advantages, the selective absorption spectra of fluorophores offers the opportunity to use wavelength-division multiplexing (WDM) to increase link capacity.^[1, 8]

In order to construct a reliable WDM link, the key challenge is to separate, at the receiver side, the individual data streams carried by different wavelengths whilst minimising link loss and crosstalk between these data streams. Applying absorbing or reflecting optical colour filters in front of individual photo-detectors is the most popular approach to WDM^[9, 10]. For example, Wu et al.^[10] reported a WDM system, which uses colour selective dichroic filters to separate individual WDM links. This structure makes all colour channels propagate along the same optical axis, maintaining collinearity, and compact design, but supports only point-to-point applications with limited FoV.

In this letter, we demonstrate a simple, inexpensive and practical device, based on fluorescent optical antennas, which can enable WDM in VLC and thus enable a further improvement in link capacity. The concept of this device is illustrated in **Figure 2**. The device is a stack of two fluorescent optical antennas each designed to preferentially absorb a particular part of the visible light spectrum and therefore concentrate a separate colour channel. The results show that this fluorescent antenna can enhance data rates, whilst also achieving good gain and FoV.

Device fabrication and characterization

The requirements for the emitting material in a fluorescent antenna are^[11]: (i) strong absorption in the emission wavelength; (ii) high fluorescence quantum yield (PLQY); (iii) excited states with a lifetime of less than 10 ns for MHz range bandwidth, preferably closer to 1 ns; and (iv) weak overlap between absorption and emission spectra. Further challenges for

materials and fabrication of a WDM enabling fluorescent antenna are: (v) a selective colour absorption of the incident light, and (vi) an effective separation and extraction of multiple wavelengths.

The two dyes which fulfil the requirements for the materials for de-multiplexing the blue and green components of the light signal are: Coumarin 6 (Cm6) and 4-(Dicyanomethylene)-2-methyl-6-(4-dimethylaminostyryl)-4H-pyran (DCM), respectively. Each material was incorporated into an antenna composed of a fluorescent layer, where the dye molecules were dispersed in a transparent epoxy matrix, sandwiched between two microscope slides. The two antennas were then stacked to make the WDM antenna. **Figure 3**, shows the basic results of the photophysics study of the two materials, with absorption spectra of the layers shown in **Figure S3**. Cm6 layer has a strong absorption in the region of the blue LED (optical density (OD) 2.25 at 465 nm), while transmitting most of the green part of the spectrum (OD below 0.1 beyond 510 nm). The absorption of the DCM layer extends into the region of the green LED's emission (OD 1.3 at 525 nm). The emission spectra do not strongly overlap, with Cm6 having an emission peak at 510 nm and DCM at 610 nm. Cm6 has a high PLQY of 80-95 %, while DCM has a PLQY of 50 %. Both dyes show a single exponential PL decay with a similar lifetime of ≤ 3 ns (see **Figure 3c**; 2.57 ns for Cm6, 2.70 ns for DCM).

The WDM data link consisted of the WDM antenna placed under an optical transmitter, with an optical detector at either end, as shown in **Figure 2**. The transmitter was a commercial multi-chip RGB LED. The blue ($\lambda_{\text{max}} \approx 460$ nm, FWHM 23 nm) and the green ($\lambda_{\text{max}} \approx 520$ nm, FWHM 36 nm) LED chips were driven by an arbitrary waveform generator, applying independent data-streams to the two sources. The intensities of both LEDs were adjusted so that the incident light on the WDM antenna from each LED was 1 W/m², with calculated lux to be 111 lux for the blue LED, and 665 lux for the green LED. For comparison, the standard

for a good illuminated office environment is 500 lux of white light (CIBSE recommended lighting levels), which corresponds to about 5 W/m² of white light from a typical blue coated blue LED.

The WDM antenna was placed 20 cm from the LED sources, with the Cm6 layer closer to the sources. Due to the high absorption of the blue part of the spectrum (450-470 nm) by Cm6, only a small portion of the blue light reached the underlying DCM layer. On the other hand, Cm6 has low absorption of green light (~520 nm), therefore most of the green light was transmitted to the layer of DCM where it was absorbed. Finally, the output from each of the fluorescent antennas was butt-coupled to a photodiode (see **Figure 2**).

The advantage of the fluorescent antenna over the traditional optics is the combination of the wide FoV and gain that it can achieve. **Figure 4** summarises the measurements of gain of the two antennas as a function of incident angle. For the Cm6 layer, the gain measured using the blue LED, is approximately 8, while for the DCM layer, the gain from the green LED, is approximately 11. In both cases, we can see from this figure that the FoV is much larger than the FoV of a condenser lens which would give a similar optical gain.

Communication performance

To evaluate the de-multiplexing capabilities of the WDM fluorescent antenna, the cross-talk between the WDM channel was measured. Like in the case of spatial multiple-input-multiple-output (MIMO) systems, the channels H matrix shows the proportions of the intended signals and the crosstalk. This can be measured by transmitting known training sequences and recording the received signal on each photodiode. Equation (1) shows both the definition of the normalised channel H matrix of the system and the measured values for the particular WDM fluorescent antenna that was tested:

$$\begin{bmatrix} S_{Cm6} \\ S_{DCM} \end{bmatrix} = \mathbf{H} \begin{bmatrix} S_{blue} \\ S_{green} \end{bmatrix}; \quad \mathbf{H} = \begin{bmatrix} 0.91 & 0.36 \\ 0.43 & 1 \end{bmatrix}; \quad (1)$$

where S_{Cm6} and S_{DCM} are the received PL signals from Cm6 and DCM, and S_{blue} and S_{green} are the transmitted signals from blue and green LED, respectively. The H matrix also indicated about the levels of fluorescent light measured by the photodiodes, for each LED. For the blue LED, about 68 % is collected by the photodiode attached to the Cm6 doped layer and 32 % by the photodiode attached to the DCM doped layer. For the green LED, these percentages are 26 % and 74 %, respectively. In terms of cross talk, the H matrix indicates that for both layers the cross-talk is about 30 %.

The values in the \mathbf{H} matrix show that crosstalk is less than half of the desired signal. To eliminate the residual inter-channel crosstalk and hence separate the channels, standard MIMO processing techniques can be used, the simplest of which is apply the inverse of \mathbf{H} (\mathbf{H}^{-1}) at the receiver (also known as zero-forcing, ZF). In the absence of noise, the product of $\mathbf{H}\mathbf{H}^{-1}$ is an identity matrix, hence the crosstalk is completely eliminated. Though the ZF enhances noise and other advanced techniques such as minimum mean square estimation (MMSE), iterative interference cancellation, or pre-coding at the transmitter exists, the performance difference of these techniques are minimal^[12]. Hence, ZF was applied in this work due to its simplicity.

In order to test the link, using on-off keying (OOK) scheme a stream of 2^{14} pseudorandom bits was transmitted to the WDM antenna. **Figure 5** shows the measured bit-error-rate (BER) as a function of the data rate for the two channels. Without channel separation, the different colour channels were indistinguishable, leading to high BERs for all data-rates (grey lines in **Figure 5**). When the WDM fluorescent antenna was used, a 1 Mb/s data rate with BER of 10^{-4} was achieved, simultaneously, for both blue and green channels. The superimposition of two OOK waveforms of different amplitude (one of these being due to the crosstalk from the unwanted

channel) can clearly be seen on the 1 Mb/s eye diagram. Despite this, a low BER link can be achieved with subsequent MIMO processing.

At higher data rates, the unprocessed eye diagrams become hard to discern due to the limited bandwidth of the photodiodes used (2 MHz). Nevertheless, after applying MIMO processing and (temporal) equalisation techniques, a good eye-opening is created at 6 Mb/s, resulting in error-free operation. An aggregate, 12 Mb/s was therefore achieved by taking advantage of the colour separating characteristic of the WDM antenna.

Higher data rates would be achieved by using higher bandwidth photodiodes. However, this experiment shows that a compact WDM antenna can be used to substantially increase available data rate, whilst maintaining a large FoV.

Conclusion

In conclusion, this letter presents a novel, yet simple and compact device, which can combine a wide FoV, high gain, and enable WDM. The device is based on a stacked two-layered fluorescent optical antenna. It has been shown that the device outperforms traditional optics (which are limited by the conservation of étendue) giving significant signal gain, combined with a large FoV. In particular, we have achieved gains of more than 8 and 11, and a wide FoV, while enabling WDM. Finally, it was demonstrated experimentally that this device can enable practical WDM VLC receivers. This approach opens a new pathway to spectrally efficient, high gain receivers with a small form factor that could be integrated into mobile devices so that they have a VLC capability.

Experimental Section

Device fabrication. The dyes Coumarin 6 (Cm6) and 4-(Dicyanomethylene)-2-methyl-6-(4-dimethylaminostyryl)-4H-pyran (DCM), were chosen for de-multiplexing the blue and green components of the light signal, respectively. The two components of the device were fabricated using the same method. Each dye was separately mixed with the UV curable

epoxy, Norland 68 (NOA68). For each solution, a concentration of 4 mg/ml was used. The solutions were prepared by weighing the appropriate mass of dye then adding the corresponding volume of epoxy. The solution was mixed, with a magnetic stirring bar for 24 hours. The ends of two microscope slides were covered in black tape that was trimmed to the same thickness as the microscope slide using a scalpel. A volume of ca. 0.25 ml of dye/epoxy solution was spread on the slide which was placed between four spacers on a flat steel plate (see **Figure S1**). The spacers were made from aluminium, in a disk shape and their thickness was chosen to be the thickness of the two microscope slides plus 100 μm . A second microscope slide was placed on top of the first slide. These were pressed together under a uniform pressure from a 3 mm thick fused silica plate so that the thickness of the antenna was defined by the spacer thickness. The epoxy was then cured by a flood UV exposure, using an 8 W UV lamp at 365 nm, for three minutes. The two components were attached to each other by an insulated tape (see **Figure S2**). Between the two components a small gap was formed (~ 0.1 mm) by using two pieces of tape as spacers.

Photophysical measurements. In order to avoid self-absorption of emission, low concentration films were used for photophysical studies. The maximum absorbance of Cm6 in NOA68 was 0.25, while for DCM in NOA68 was 0.4. The absorbance of the films was measured with a Cary 300 (Varian Inc.) spectrophotometer. The photoluminescence (PL) spectra and lifetimes were measured with a FLS980 fluorimeter (Edinburgh Instruments Ltd.) with an excitation wavelength of 450 nm. PL lifetime measurements were taken using the FLS980 with a PicoQuant laser, exciting at 375 nm to excite the sample and a photomultiplier tube (PMT) for detection. The photoluminescence quantum yield (PLQY) was measured with an integrating sphere^[13] (Hamamatsu integrating sphere C9920-02 Luminescence measurement system) under excitation at 450 nm.

Gain measurements. The gain for different channels was measured by placing the device on a rotating stage and comparing it to the incident power. The measurements for lens gain were

done by a condenser lens ACL50832U (Thorlabs), where the APD430A (Thorlabs) was used as a detector. The spot size was adjusted by positioning the lens at an appropriate distance from the detector, so that to achieve gain similar to that of the fluorescent concentrator. For illumination diode laser D405-120 was used (Digikey), with an engineered diffuser ED1-S20(-MD) (Thorlabs).

Data communication measurement. The LEDs used were LZ4-00MC00 (LED Engine Inc.) with a bandwidth of 4 MHz. The S2387-130R (Hamamatsu) silicon photo-detectors, with an effective active area of 35 mm² and bandwidth of 2 MHz, were aligned to the edges of the WDM fluorescent antenna (see **Figure 2**). An arbitrary waveform generator (Agilent 81150A) and real-time storage oscilloscope (Agilent MSO7104B) were used for the BER vs. data-rate measurement.

Figure 1. Examples of achievable fields-of-view and optical gain for different optical receivers. a) The maximum theoretical gain for a compound parabolic concentrator with a field-of-view of 25°. b) The maximum theoretical gain for a compound parabolic concentrator with a field-of-view of 45°. c) Experimental results for the field-of-view and gain of a fluorescent antenna^[6].

Figure 2. Schematic representation of the WDM fluorescent antenna. The transmitted signal is multiplexed and drives blue and green light emitting diodes (LED). The receiver consists of a layer of Coumarin 6 attached to a photodiode (PD) and a layer of DCM attached to another PD. The blue light is primarily absorbed by the Coumarin 6 layer and the green light by the DCM layer. The resulting fluorescence is guided to the edges of the device, where it is detected by the two PDs. Each of the PDs is attached to a different layer and therefore primarily receives the signal encoded into the blue or green wavelength channel. Due to the geometry of the antenna, the SNR is enhanced, while the angular response of the detector is proportional to the cosine of the angle of incidence, giving a wide field-of-view.

DEVICE FABRICATION

Fluorescent antenna fabrication. Figure S1 depicts the details of the fabrication process. The dyes Coumarin 6 (Cm6) and 4-(Dicyanomethylene)-2-methyl-6-(4-dimethylaminostyryl)-4H-pyran (DCM), were chosen for de-multiplexing the blue and green components of the light signal, respectively. The two components of the device were fabricated using the same method. Each dye was separately mixed with the UV curable epoxy, Norland 68 (NOA68). For each solution, a concentration of 4 mg/ml was used. The solutions were prepared by weighing the appropriate mass of dye then adding the corresponding volume of epoxy. The solution was mixed, with a magnetic stirring bar for 24 hours. The ends of two microscope slides were covered in black tape that was trimmed to the same thickness as the microscope slide using a scalpel. A volume of ca. 0.25 ml of dye/epoxy solution was spread on the slide which was placed between four spacers on a flat steel plate (see fig. S1). The spacers were made from aluminium, in a disk shape and their thickness was chosen to be the thickness of the two microscope slides plus 100 μm . A second microscope slide was placed on top of the first slide. These were pressed together under a uniform pressure from a 3 mm thick fused silica plate so that the thickness of the antenna was defined by the spacer thickness. A flood UV exposure, using an 8 W UV lamp at 365 nm, for three minutes followed to cure the epoxy.

Figure S1. Schematic representation of fluorescent antenna fabrication process. From top-down: initially, a small volume of dye/epoxy solution is spread on a microscope slide (see top part of the figure above), a second slide is placed on top, the slide/solution/slide layer is pressed between two fused silica windows where the space between them is defined by spacers, and the final stage is an UV curing of the solution.

WDM fluorescent antenna fabrication. The two components, of the WDM fluorescent antenna, were attached to each other by insulating tape (see fig. S2). Between the two components a small gap was formed (~ 0.1 mm) by using two pieces of tape as spacers.

Figure S2. Schematic representation of how the WDM antenna was made. Two fluorescent antennas were held together by insulating tape, and insulating tape was also used as spacer between them. Finally, the two components are attached by an insulating tape.

DEVICE ABSORBANCE
